## ANTICOAGULANT TREATMENT OF POSTOPERATIVE VENOUS THROMBOSIS AND PULMONARY EMBOLISM\*

JAMES A. EVANS, M.D.,† AND JOHN F. DEE, M.D.‡

BOSTON

ANTICOAGULANT treatment is winning for itself a firm place in the armamentarium against postoperative venous thrombosis and pulmonary embolism. This has been accomplished by the sheer weight of accumulating statistics from various clinics, both in this country and in Sweden.<sup>1-22</sup> Since April, 1941, when dicumarol first became available, the drug has provided the predominant method of therapy at the Lahey Clinic. In the majority of cases a combination of heparin and dicumarol has been used. During the first four years heparin was given by continuous intravenous drip to cover the latent period of dicumarol. For the past two years deep injections of Loewe's<sup>22,21</sup> heparin in Pitkin menstruums<sup>9</sup> have been given subcutaneously.

In this series of 184 cases, occurring from 1942-1946, venous ligation was also performed in 10 cases. The two systems of treatment, venous ligation and administration of heparin in Pitkin menstruum, should not be considered rival methods but rather complementary to each other. Our confidence in the efficacy of anticoagulant therapy, however, has grown through these five years to such an extent that the indications for venous ligation have dwindled to the following conditions: hemorrhagic disease, severe liver disease, second-stage operation, ambulatory phlebotrombosis with pulmonary embolism (Homans), resistance to both heparin and dicumarol, recurrence of benign embolism after supposedly adequate treatment, prophylactic ligation in patients over sixty years of age for expected bleeders (prostatic resection), and prophylactic ligation in patients over sixty who are debilitated from cancer or other causes (Miles resection). Ligation in elderly patients who are debilitated from cancer or other causes is regarded as only a rela-

tive indication to be used at the surgeon's judgment, because in the Lahey Clinic it would add the insurmountable surgical burden of about three or four thousand ligations a year. Therefore, prophylactic exercises, early ambulation and dicumarol prophylactically are preferred on the fourth day after operation.

Although it must be admitted that the vagaries of dicumarol resistance and sensitivity in different patients and the pitfalls of accurate prothrombin estimations should limit its use to the experienced and wary clinician equipped with a very reliable laboratory, it is believed that the advent of heparin in Pitkin menstruum will popularize anticoagulant therapy as a safe and reliable method of treatment. This will occur when the menstruum is more widely available and the cost of this product has dropped. Loewe<sup>21</sup> now claims that more careful buffering of the menstruum has overcome the frequent painfulness of the deposit in the tissues. This makes it possible to give more numerous injections than when heparin in Pitkin menstruum is combined with dicumarol. Up to the present time we have not had the opportunity of using this allegedly more painless formula. Unless the production of pain can be overcome, protracted treatment with many injections will be limited.

After five years' experience with anticoagulant therapy we have evolved the following set of rules—applicable to all patients kept lying in bed—for instruction to the staff:

As a precaution against thrombosis and embolism, the patient should be instructed to wiggle the toes and feet one thousand times daily, including pressing the soles of the feet against the foot of bed if possible.

If the patient has varicose veins, elastic bandages are to be used twenty-four hours a day until he is ambulatory.

The patient should be asked daily on rounds if there is pain in the calf, and inspected for sore-

ness in the calf and for Homans's sign, especially if unexplained fever is present

A stamp has been provided for history charts, entitled "History of Venous Thrombosis or Pulmonary Embolism" This should be stamped on every history and filled in. If a patient with such a history comes to surgery, he should re-

FIGURE 1 Course in a Typical Case Successfully Treated with Anticoagulants

Any part of the coagulation time above the heavy black horizontal line represents the anticoagulant effect of heparin, any part of the prothrombin line above the same black line represents what is considered a fairly safe antithrombotic effect of dicumarol—namely, a prothrombin level below 65 per cent. We strive to keep the prothrombin percentage between 40 and 50.

ceive postoperative anticoagulant therapy after consultation between the surgical and medical departments

Such treatment should be started routinely four days after operation, five days after gall-bladder surgery or on a later day if deemed advisable by the surgeon. Dicumarol only is necessary for such prophylactic therapy, and therefore only the prothrombin time should be determined.

No anticoagulant therapy is given to patients with severe liver disease or hemorrhagic diseases or to those who are soon to undergo a second operation.

The routine after carotid-artery ligation, immediately after return from the operating room, includes 100 mg of heparin in Pitkin menstuum without a vasoconstrictor, 100 mg of heparin in Pitkin menstuum with a vasoconstrictor and 200 mg of heparin in Pitkin menstuum with a vasoconstrictor if the patient weighs over 150

pounds. Only one such injection, deep subcutaneously, should be given, and no coagulation-time control is necessary.

For routine anticoagulant therapy, the prothrombin and coagulation times should be controlled.

Heparin in Pitkin menstuum—100 mg—without a vasoconstrictor and heparin in Pitkin menstuum—100 mg—with a vasoconstrictor should be injected deep subcutaneously, if the patient weighs over 150 pounds, 200 mg with a vasoconstrictor should be injected deep in the subcutaneous tissues.

Dicumarol (200 mg) should be given—300 mg if the patient weighs over 150 pounds.

Daily morning determinations of the coagulation time and prothrombin percentage are necessary.

A daily maintenance dose of 50 to 100 mg. of dicumarol should be administered to keep the prothrombin between 50 and 60 per cent.

No dicumarol should be given until the morning prothrombin time is known for that day.

If the patient proves refractory to dicumarol, the same dosage of heparin in Pitkin menstuum should be given until the coagulation time comes back to normal, usually every third day.

Heparin in Pitkin menstuum should be discontinued when the prothrombin drops to 60 per cent, and coagulation-time determinations should be stopped.

For any bleeding, the prothrombin time, as well as the coagulation time if the patient is also receiving heparin, should be determined, and 60 mg of vitamin K given intravenously. This procedure is repeated every six hours until the prothrombin time is normal, which takes from eight to forty-eight hours. Fresh-blood transfusions should be given if indicated to give undeteriorated prothrombin. A transfusion is needed to counteract the effect of the heparin, and vitamin K to counteract that of dicumarol. Ice bags should be applied to the heparin in Pitkin menstuum deposit.

The patient is to be ambulatory when the temperature has returned to normal and local signs of venous thrombosis (except swelling) have disappeared, if the surgical department permits and if the anticoagulant effect is present.

Paravertebral sympathetic blocks should be employed if signs of reflex arterial spasm (swelling, white limb, absent pulses and pain) are present.

A heat cradle should be applied to the legs.

For pulmonary embolism, 0.6 to 0.12 gm of papaverine should immediately be injected intravenously.

Figure 1 illustrates a typical successfully treated case. A majority of patients in this series were

allowed out of bed within ten days of the beginning of therapy

The fact that anticoagulant therapy can do nothing to prevent the fragile red clot of phlebothrombosis from breaking off is the chief argument advanced by the opponents of this method of treatment. Three facts assure protection against this hazard. Loewe,<sup>22</sup> in a recent communication, has shown that heparin actually causes this "sludge" type of clot to disappear in animal experiments *in vivo* (whether dicumarol actually has a similar effect has never, to our knowledge, been proved), statistics have accumulated to prove that the actual subsequent pulmonary emboli to be expected statistically do not occur, and metastasis of the bland phlebothrombosis clot results from very fresh, unrecognized foci and rarely from clinically recognizable foci. Such dangerous new areas of phlebothrombosis are prevented from forming.

Death from pulmonary embolism is also made less likely by the prevention of propagation of a thrombus already present in the pulmonary arterial tree. This fact leads to the rule of permitting patients to be out of bed only when a good anticoagulant effect obtains.

The advantages of anticoagulation are as follows: avoidance of another operation, usually on a very sick patient; avoidance of danger of swelling in some cases; avoidance of danger of arterial thrombosis and gangrene in arteriosclerotic patients; inhibition of spreading thrombotic disease in systemic veins and in pulmonary arteries if a benign embolism has already occurred; no hesitation to institution of anticoagulant therapy in very doubtful cases; statistical proof from several clinics that anticoagulation prevents subsequent fatal pulmonary embolism, and decreased incidence of postphlebotic venous stasis and ulcer (Bauer<sup>23</sup>).

### RESULTS

There were 184 cases of postoperative venous thrombosis with or without pulmonary embolism during the five years 1942-1946. Sixty-three patients received heparin intravenously, 2 of them by the intermittent, Swedish method. Fifty-five received heparin in Pitkin menstruum. One to five injections of heparin in Pitkin menstruum were necessary according to the patient's refractoriness to dicumarol. Three patients received heparin only. Sixty-three patients received dicumarol only. Twenty-seven patients, or 15 per cent, were considered refractory to dicumarol. All such patients now receive heparin in Pitkin menstruum to keep them in control. A patient was considered refractory when the prothrombin level did not fall below 65 per cent despite ordinarily adequate doses. Fortunately, only 1 death occurred among the refractory patients, but this is not considered an excuse to administer dicumarol without adequate control

of dosage by determination of the daily prothrombin levels.

Sixty-one of the 184 patients, or 33 per cent, had a warning benign pulmonary embolism (Table 1). To the 184 cases must be added 54 patients who had postoperative pulmonary embolism and who died untreated, because such deaths either occurred suddenly or were unrecognized as thrombosis with embolism. This makes a total of 238 cases of thromboembolic disease in five years, or an incidence of 0.42 per cent among approximately 56,000 major surgical operations performed at the New England Deaconess and New England Baptist hospitals by the surgeons of the Lapey Clinic. This low incidence

TABLE 1 *Incidence of Venous Thrombosis and Pulmonary Embolism among 56,000 Major Surgical Operations (1942-1946)*

POSTOPERATIVE COMPLICATION	NO. OF CASES
Venous thrombosis without embolism (treated)	123
Venous thrombosis with warning pulmonary embolism (treated)	61
Sudden or unrecognized fatal pulmonary embolism (not treated)	54
Total	238 (0.42%)

was due to the assiduous care of the nursing staffs of these two hospitals in seeing that the patients carried out proper prophylactic exercises. That such precautions were largely responsible for the results is strongly suggested by the fact that in three winter months at the start of our campaign against pulmonary embolism the incidence in a hospital where the staff had not yet received instructions to carry out these exercises was three and a half times that in another hospital, where the exercises were practiced, the number of cases being 7 and 2 respectively.

There were 6 fatal cases in the series of 184 patients. Two were postoperative chemical deaths. One patient early in the series died of hemorrhage from dicumarol poisoning, because at that time the value of the rule never to give the daily dose of dicumarol until that morning's prothrombin time is known was not appreciated. This leaves 3 fatal cases of thromboembolic disease. One patient received inadequate doses of dicumarol, and a prothrombin level within the therapeutic range was never obtained; he was also given a transfusion, which destroyed any slight effect the dicumarol might have had, and he died of a second pulmonary embolism a few hours later. Another patient died a few hours after a single pulmonary embolism, in spite of one dose each of heparin in Pitkin menstruum and dicumarol given when he was in extremis. He would not have been saved by venous ligation, unless it had been done prophylactically at the time of operation. The cause of death in the

third case was declared sepsis by the pathologist. The patient had received adequate anticoagulant control throughout, but died of a septic infarct with pyopneumothorax and septic peritonitis.

It has long been recognized that a warning benign pulmonary embolism increases greatly the chance of a subsequent fatal embolism. In all 3 fatal cases a warning embolism had occurred. There were 61 cases in the series in which a warning was given by a benign infarct to the lung—a mortality of 5 per

cent never had a warning infarct. This fact points up the danger to the patient who has had a warning embolism.

### COMPLICATIONS

Bleeding was recorded in 12 cases (Table 2). It was of a serious nature, requiring transfusions or vitamin K, or both, in 5. Two cases required heroic treatment with repeated doses of 60 mg of vitamin K and transfusions totaling as much as 2750 cc of blood. There was 1 fatal case of bleeding into the wound early in the series before vitamin K was known to be an antidote for dicumarol.

Vitamin K has made dicumarol much safer to use. For prothrombin levels as low as 20 per cent, we have often given booster doses of 40 mg of vitamin K (either Hiquinone or Synkavite), bringing the prothrombin level to a safer therapeutic range but not losing the anticoagulant effect. For serious

cent in this category, or 1.6 per cent for the entire series. In the past two years, since the use of heparin in Pitkin menstruum as well as dicumarol and with better control of the anticoagulant effect by continued administration of heparin subcutaneously until a good dicumarol effect is obtained, only 1 death has occurred—that of the patient with sepsis mentioned above.

There were benign recurrences of pulmonary embolism in 2 of the 61 patients who had warning

FIGURE 2 Mortality from Postoperative Pulmonary Embolism. Note the decreasing rate after institution of anticoagulant therapy, in 1942, together with institution of prophylactic exercises and increased watchfulness for signs of thromboembolic disease.

TABLE 3 Warning Signs in 52 Fatal Cases of Pulmonary Embolism (1940-1945)

TYPE OF CASE	No. OF CASES	WARNING SIGNS* NO. OF CASES
Death in 1 hour	22	16
Death in 2-24 hours	20	18
Death 1-24 days after first benign pulmonary embolism	10	10

\*Warning signs included fever and tachycardia, varicose veins, previous history of thrombosis or embolism and premonitory pulmonary embolism.

benign pulmonary infarcts. One of these occurred after only four days and after treatment had been abandoned. Further heparin in Pitkin menstruum combined with dicumarol was given, with recovery. In the other patient dicumarol had also been stopped when a subsequent embolism occurred. Bilateral ligation was then performed, with recovery. The prothrombin level at the time of infarct was not stated in the records of either patient.

There was no occurrence of either fatal or benign pulmonary infarct among the 123 patients who

bled; we recommend 60 mg intravenously, repeated two or three times a day, together with transfusions of fresh citrated blood. Bank blood is too low in prothrombin content but may be used for blood replacement. We have had no experience with protamine as an antidote for heparin.

There has been no incidence of hematomas at the site of injection of heparin in Pitkin menstruum in over 55 patients receiving eighty-three injections.

### DISCUSSION

There still remains the problem of the sudden deaths from pulmonary embolism occurring before there is an opportunity to treat the patient. The results reported above give us great confidence in trusting anticoagulant therapy in the recognized cases of postoperative venous thrombosis. During the five years under study 59 patients died of pulmonary embolism, in 27 the diagnosis was proved at autopsy, 4 cases in this category occurring in medical patients. This situation must be met by eternal watchfulness of the postoperative and bed-

ridden patient. Here, too, lies a field for more prophylactic ligations as done by Allen, Linton and Donaldson<sup>26</sup> in the debilitated patient over sixty years of age. Dicumarol should be used prophylactically more often, and we give this treatment routinely to patients with a history of thrombophlebitis or embolism following a previous operation or childbirth. Our results in the prophylactic use of dicumarol will be the subject of a future report.

In addition to the routine daily examination of legs postoperatively, more attention must be paid to the temperature and pulse chart. A recent analysis of 52 cases of death from pulmonary embolism revealed that 85 per cent of the patients gave warning signs of rise in temperature or pulse, or both, or had varicose veins or a previous history of thrombotic disease (Table 3).<sup>8</sup>

That our efforts to prevent death from postoperative pulmonary embolism have not been in vain is shown in Figure 2. The mortality was cut to one fourth in 1945 and to one half in 1946. The rise during the last year shows the need of guarding against complacency and of still greater alertness on the part of all services to attain what should no longer be considered an impossibility: a deathless year from pulmonary embolism. More prophylaxis by both venous ligation and anticoagulation seems to be the answer. The former is impractical in a large surgical service except in cases considered most susceptible. Prophylactic exercises, bandaging of varicose veins, early ambulation and anticoagulant therapy must be used for the larger majority of patients considered to be susceptible. Anticoagulant therapy is adequate for postoperative patients who already have developed thrombosis with or without pulmonary embolism.

### SUMMARY

Anticoagulant treatment by heparin or heparin in Pitkin menstruum in combination with dicumarol offers a safe, practical method to prevent postoperative death from pulmonary embolism.

The recent introduction of heparin in Pitkin menstruum injected subcutaneously has greatly simplified anticoagulation. This therapy has the added advantage of producing an anticoagulative effect that can easily be kept up as long as necessary in the dicumarol-refractory patient.

Of 184 patients with postoperative venous thrombosis with or without warning pulmonary embolism, 3 patients died of thromboembolic disease — an incidence of 1.6 per cent. These 3 deaths occurred in the particularly dangerous group of cases in which the patients had already suffered one pulmonary embolism, and represented a mortality of only 5 per

cent in this category. On analysis, none of these 3 cases presented a clear-cut argument against the efficacy of anticoagulation therapy.

Since 85 per cent of patients with fatal pulmonary emboli give warning signs, usually a low temperature and tachycardia or a history of previous thromboembolic disease, or have varicose veins, a plea is made for better prophylaxis. This can be accomplished by leg exercises, bandaging of limbs, early ambulation, prophylactic ligation in debilitated patients over sixty years of age or the administration of dicumarol on the fourth day after operation.

## THIOURACIL AND ALLIED DRUGS IN HYPERTHYROIDISM\*

ELMER C BARTELS, M D †

BOSTON

THE introduction by Astwood of new and potent antithyroid substances has permitted a great advance in the treatment of hyperthyroidism and has given a new tool with which to further knowledge of the pathological physiology of diseases of the thyroid gland. This report deals with the clinical application of these drugs, which are capable of reducing to normal the elevated basal metabolic rate of hyperthyroidism resulting from either primary hyperthyroidism or adenomatous goiter. With the fall in the basal metabolic rate there is gradual amelioration of all hyperthyroid signs and symptoms except those of the eye, if these signs are marked when therapy is begun. Those who have had experience with the use of thiouracil and allied drugs must now report their results so that proper evaluation can be made. Particularly, the early overoptimistic statements regarding their supposed curative properties must be assayed.

## ACTION

When the drugs are administered in adequate doses, the production of thyroxin is halted as shown by a reduction in the blood protein-bound iodine and in the iodine content of the thyroid gland. The basal metabolic rate drops, and if the agent is continued sufficiently long, myxedema results and is maintained as long as the drug is given. Unlike the antithyroid action of iodine, which produces striking histologic improvement in the thyroid gland in primary hyperthyroidism with lessening of symptoms, thiouracil and its allied substances, although affording striking effects upon the clinical and metabolic picture, cause no change in the histologic picture. The hyperplasia of the thyroid gland may even increase. In determining whether or not these drugs will provide a substitute for subtotal thyroidectomy, it must be recognized that the histopathologic change (hyperplasia), which originally brings about hyperthyroidism, is still present even after the basal metabolic rate has been effectively restored to normal.

It was initially supposed that these drugs acted by preventing the thyroid gland from absorbing iodine. Clinical experience, however, revealed this to be incorrect, since it was found that the administration of Lugol's solution produced involution of the thyroid gland even when thiouracil was being administered. This was demonstrated by an in-

crease in the firmness of the gland, a lessening or disappearance of the bruits and thrills at the superior poles and a marked reduction in the vascularity of the gland at operation in patients receiving Lugol's solution in conjunction with thiouracil. A comparison of patients receiving thiouracil alone and those receiving both thiouracil and iodine showed that there was substantially more iodine in the thyroid glands of the latter (Fig 1). It was then reported by McGinty and Sharp<sup>2</sup> that the iodine absorbed by additional iodine feeding to rats receiving thiouracil or propylthiouracil is not synthesized into a protein-bound form but remains in the gland as iodide. This indicates that these antithyroid substances act by preventing the synthesis of iodide to an active protein-bound hormone — diiodotyrosine and thyroxin (Fig 2). The thiocyanate ion, on the other hand, has a specific effect upon the thyroid gland in that it interferes with the mechanism that permits the gland to hold the iodide ion and does not seem to interfere with the synthesis of the thyroid hormone.<sup>3</sup>

The selective mechanism by which thiouracil and its allied substances interfere with the organic blending of iodide is as yet not certain. Studies by DeRobertis<sup>4</sup> warrant the conclusion that these substances probably act by inhibiting the peroxidase or enzymatic system in the thyroid gland that functions to oxidize iodide to form the protein-bound or active thyroxin molecule.

## DOSAGE

The effective daily dose of thiouracil was established from the very outset to be 600 mg. Thiobarbital, which was next given a therapeutic trial, was found to affect the metabolism beneficially in a single dose of 50 mg a day. The dose of propylthiouracil, which was initially suggested as 50 to 100 mg daily, was found to be inadequate, since it did not produce a response comparable to that obtained with a daily dose of 600 mg of thiouracil. Some patients responded to 75 mg a day, but it was not until the daily dose had been increased to 200 mg that uniformly satisfactory improvement was accomplished in all cases. Larger doses, up to 600 mg a day, have been used in a few cases without a significant difference in clinical response to that obtained with 200 mg. For patients with large adenomatous goiters, whose response to therapy is always slow, a daily dose of 300 mg is given.

Propylthiouracil, the drug that we now employ exclusively, is administered in a dosage of 100 mg.

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1947.

every twelve hours (100 mg at 8 a.m. and 100 mg at 8 p.m.) In a few patients the entire dose, 200 mg, was administered once a day with a clinical response that was as effective as that to the divided doses.

### Toxicity

Since the three agents with which we have had experience are equally effective in lowering the basal metabolic rate, the choice of agent for clinical use is dependent on the percentage of reactions to each. Of the three, thiobarbital had the highest incidence of complications, 28 per cent, thiouracil, 9 per cent, and propylthiouracil is much the safest, 1.6 per cent, or six reactions in 430 cases.

The reactions to thiouracil consisted of depression of the white-cell count, fever, swollen salivary glands, skin rash and edema of the skin, with 1 fatal case of agranulocytosis. Thiobarbital primarily affected the white-cell count and occasionally caused fever. The six definite reactions to propylthiouracil included depression of the white-cell elements in 5 patients and fever in 1, the blood changes were variable (Fig. 3), comprising granulocytopenia without leukopenia, or leukopenia without granulocytopenia and various degrees of depression of both the leukocytes and granulocytes. One patient developed agranulocytosis, this patient recovered after penicillin therapy. These experiences indicate that propylthiouracil is by far the safest drug but force the conclusion that it is not entirely unattended by significant side effects.

### REMISSION AND RELAPSE

It was hoped by all and prematurely reported as established by some that these new drugs had, in

was suggested as a means of effecting the desired result. Wider experience by many physicians soon indicated that prompt relapse of hyperthyroidism followed a reduction of the dose or withdrawal of

FIGURE 1 Comparison of the Iodine Content of the Thyroid Gland following the Administration of Thiouracil with That following the Administration of Combined Thiouracil and Iodine (Reproduced from Lukry et al. by Permission of the Publishers)

the drug in many cases, irrespective of the duration of active therapy. In other cases prolonged remissions occurred after discontinuance of treatment. The percentage of remissions produced and the percentage of relapses vary widely in the available

FIGURE 2 Schematic Comparison of the Normal Thyroid Function as Affected by Thiouracil and Potassium Thiocyanate

addition to the capacity to reduce the basal metabolic rate to normal, the property of producing a sustained remission of hyperthyroidism in a high percentage of patients. A year of continued therapy

reports. My experience indicates that prolonged remission (we prefer to designate the hyperthyroid-free period as remission and not cure) occurs in some patients with mild hyperthyroidism in whom

the thyroid enlargement is but slight and that the duration of treatment has little to do with the duration of the remission so long as the basal metabolic rate is normal when the drug is withdrawn (Fig 4). Likewise, relapse in two to six months was observed after reduction of the dose or on withdrawal of antithyroid therapy in patients with a high degree of hyperthyroidism and sub-

primary hyperthyroidism and adenomatous goiter under antithyroid treatment. Actually, the basic etiologic cause of hyperthyroidism must be determined before the occurrence of relapse or remission of hyperthyroidism as affected by antithyroid therapy is understood.

### MAINTENANCE THERAPY

The use of antithyroid drugs as maintenance treatment, which is necessary in a high percentage of cases if medical treatment is to be utilized and thyroidectomy avoided, carries with it certain specific disadvantages. It must, however, be admitted that by a carefully regulated daily dose of these drugs, hyperthyroidism can be adequately controlled for a prolonged period. Proper regulation

FIGURE 3 Significant Changes in the Total White-Cell Count and Polymorphonuclear Percentage during the Administration of Propylthiouracil (Reproduced from Bartels<sup>6</sup> by Permission of the Publishers)

stantial thyroid enlargement, in spite of prolonged therapy (Fig 5).

Since a large proportion of the patients who are referred to the Lahey Clinic for care have severe hyperthyroidism, a program of treatment aimed at inciting a remission would hold little chance for success. Whether the recently suggested plan of producing hypothyroidism before withdrawal of treatment<sup>7</sup> will result in a higher percentage of remissions or in more prolonged remission, only further observation will decide. From the histopathological standpoint, since the enlarged thyroid gland is present and still hyperplastic and the adenomatous gland remains as before, it is expected that this plan would only delay the inevitable relapse that follows. It has been reported that prolonged treatment leads to exhaustion and atrophy of the thyroid gland. We have observed the gland to decrease in size in a few patients with mild hyperthyroidism with only slight thyroid enlargement who have remained in prolonged remission. We have also observed, however, substantial increases in the size of the thyroid gland of patients with

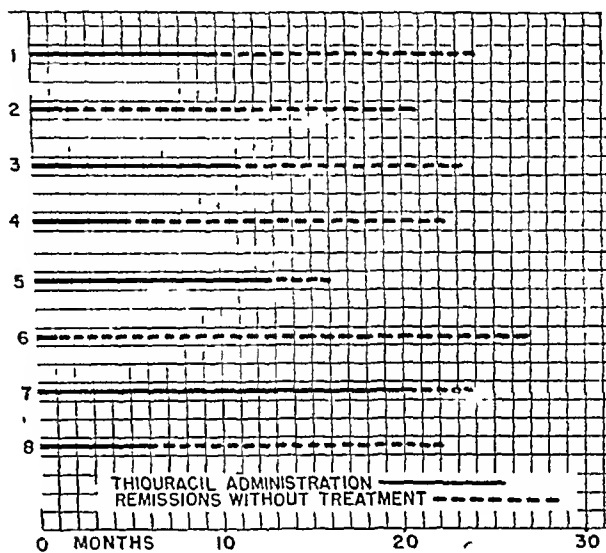

FIGURE 4 Prolonged Remission after Treatment with Thiouracil in Mild Hyperthyroidism with Slight Thyroid Enlargement (Reproduced from Bartels<sup>6</sup> by Permission of the Publishers)

entails periodic observations, which must include determination of basal metabolic rates and blood studies, and in the event of intercurrent illness further adjustment of the dose may become necessary, as with insulin therapy in diabetes. There are many serious objections to permitting patients to continue in a state of only partial control of hyperthyroidism, especially patients in the older age group, those with associated heart disease and those patients with psychotic tendencies. This fact must be emphasized since at present we are seeing a great many hyperthyroid patients whose disease is only partially controlled or with relapsing hyperthyroidism who can ill afford further systemic depletion. Complete control is not accomplished chiefly because of inadequate observation or understanding of antithyroid therapy on the part of the physician or the well recognized tendency of patients

to alter or discontinue therapy in the event that symptoms or signs appear that are unattributable to the medication that is being administered.

Other serious objections to maintenance treatment include such important factors as failure to bring about cure of the hyperthyroidism, persistence of goiter, inherent dangers in not removing adenomatous goiters, possible reactions to the medication, and possible development of serious histopathological change in the thyroid gland.

All these objections must be given careful consideration when maintenance management is under-

22 per cent.<sup>8</sup> With this knowledge added to other objections, including tracheal deviation and compression, it seems unwise to discard thyroidectomy in this type of goiter in which the results have been so completely satisfactory. The possibility of a reaction to the medication, although small, is real, and past experience has shown that there is no time during which one can feel entirely safe with their administration. Recent experimental work by Money and Rawson<sup>9</sup> on the prolonged use of thiouracil in rats has shown the development of cystadenomas in the thyroid gland, which appear to have malignant potentialities. Whether similar changes will occur in thyroid glands in human beings or whether administration of Lugol's solution

FIGURE 5. Relapse of Hyperthyroidism after Treatment with Thiouracil in Severe Hyperthyroidism with Substantial Thyroid Enlargement (Reproduced from Bartels<sup>8</sup> by Permission of the Publisher).

taken. Few patients are likely to choose prolonged treatment that in the end is not curative when a satisfactory surgical approach is available. The continued presence of the goiter, even though it is inactive, connotes potential trouble and indicates to the patient that he has not been cured of his disease. Over the years surgeons interested in thyroid disease have taught the advisability and urged the removal of adenomatous goiters, especially if single. Removal of such goiters seems necessary because of the possibility of malignant change, which some investigators have placed as high as

FIGURE 6. Simultaneous Administration of Propylthiouracil and Lugol's Solution Producing Rapid Initial Drop in the Basal Metabolic Rate Followed by a Slow Fall to Normal.

mitigates the danger of these tumor formations is not known.

#### ADJUNCT TO THYROIDECTOMY

Our chief experience with the antithyroid drugs has been in the field of preparing patients for thyroidectomy. It has been found that when treatment with these drugs is carefully managed, subtotal thyroidectomy can be carried out without risk, and hyperthyroid reactions during anesthesia and after operation, which in the past have caused great concern, are completely eliminated. Initially only severely hyperthyroid patients were treated preoperatively with these drugs, but since propylthiouracil has been available an increasing number of such patients are receiving the drugs. Patients with milder hyperthyroidism, however, are still prepared with Lugol's solution alone.

When these drugs are employed as a preoperative agent it is essential that they be used until full benefit is obtained, which is indicated by complete relief of all hyperthyroid signs and symptoms and return of the basal metabolic rate to nearly normal. Furthermore, it is advisable to maintain certain

patients at a normal metabolic level for a month or more before proceeding with thyroidectomy. These include patients in the older age group, those with long-standing hyperthyroidism, especially owing to adenomatous goiter, those who have suffered great visceral depletion, thyrocardiac patients in whom it is advisable to restore the heart to normal compensation and reserve and patients with related or unrelated psychoses.

Early in our experience, Lugol's solution was given for three weeks before operation to overcome the vascularity of the thyroid gland that occurs with thiouracil treatment when patients with primary hyperthyroidism are prepared for thyroidec-

tomies, and two days of treatment is required for each percentage of elevation of the basal metabolic rate.

In the last four years 830 patients have been prepared for thyroidectomy with antithyroid drugs, thiouracil being used in 381, thiobarbital in 28 and propylthiouracil in 421 patients. There was 1 death on the second postoperative day owing to coronary disease—an operative mortality of 0.12 per cent (Fig. 7) as compared with 1.49 per cent prior to the preoperative use of these drugs. Two-stage operations have been reduced from an average of 16 per cent to practically nil—only one such operation was done in 1946, and one so far in 1947.

Those who champion the medical treatment of hyperthyroidism condemn thyroidectomy as a useful procedure. We believe, as a result of our experience, that proper preparation of the hyperthyroid patient with antithyroid drugs followed by thyroidectomy offers the best chance of restoration to health in the shortest period of time with minimal risk. The objections to thyroidectomy (the incidence of tetany or unilateral vocal-cord paralysis should not be greater than 0.5 per cent) are usually surmountable. Of these two conditions, only tetany is admittedly an objectionable condition requiring careful and prolonged therapy. Myxedema, which occurs in 2 per cent of cases, is not greatly objectionable, since it can be easily and completely controlled by a daily dose of desiccated thyroid. Myxedema may actually be welcomed by those who fear a recurrence of hyperthyroidism. The recurrence rate after two years in those patients treated preoperatively with antithyroid drugs is 2 per cent, half these patients required reoperation for removal of thyroid remnants, and half obtained full control after a daily dose of Lugol's solution. Therefore, thyroidectomy after proper preoperative treatment resulted in cure in 95 per cent, with only tetany or recurrence representing a serious disadvantage.

#### SUMMARY

The new antithyroid drugs, if properly administered, will lower the basal metabolic rate of all patients with primary hyperthyroidism or adenomatous goiter with hyperthyroidism. All signs and symptoms of hyperthyroidism except prominence of the eyes subside, if present at the beginning of treatment.

Present information indicates that these drugs act on the thyroid gland by preventing the synthesis of stored iodide to an active protein-bound hormone.

The comparative effective daily doses of thiouracil and propylthiouracil are 600 mg and 200 mg, respectively.

The toxicity incidence of thiouracil is 9 per cent, and that of propylthiouracil 1.6 per cent. Therefore, propylthiouracil is the drug of choice, but since it may affect the white-cell elements its use is not without danger.

FIGURE 7 Comparison of the Percentage of Hemithyroidectomies Done before and since the Use of Antithyroid Drugs (Also, the Decrease in the Operative Mortality from 1.42 to 0.12 per cent is Shown)

tomy. Now patients receive propylthiouracil and iodine simultaneously from the beginning of treatment. With this new plan (Fig. 6), improvement starts promptly owing to the quick action of Lugol's solution, and through the action of propylthiouracil, improvement is sustained until full control of the hyperthyroidism is obtained. Iodine therapy, therefore, has two important functions: one of aiding in early clinical improvement, and the other of reducing the vascularity of the thyroid gland in preparation for easy thyroidectomy.

The use of Lugol's solution with propylthiouracil from the onset\* of therapy has delayed the ultimate recovery in that the average drop in the basal metabolic rate is now estimated as 1 per cent and 0.8 per cent as compared with 1.3 per cent and 1 per cent, respectively, in patients with hyperthyroidism of short duration and those with long-standing hyperthyroidism. The slowing effect of Lugol's solution, however, is not objectionable, since it is outweighed by the rapid clinical improvement. Patients with adenomatous goiter do not require

\*Further studies show that patients who have primary hyperthyroidism with large goiters should be treated by the old plan since response to therapy may be indefinitely delayed by the use of both Lugol's solution and propylthiouracil from the beginning of treatment.

Prolonged remission of hyperthyroidism after antithyroid treatment may occur in cases of mild hyperthyroidism with slight thyroid enlargement. In cases of severe hyperthyroidism with sizable goiters the incidence of prolonged remission is low.

Management therapy with antithyroid drugs is possible, but this type of treatment has some objections, including certain definite risks.

As preoperative adjuncts to thyroidectomy these new drugs have filled a great need and if properly used permit the elimination of operative reactions and mortality.

## NEUROLOGIC DISTURBANCES WITH FOLIC ACID THERAPY\*

PHILIP F. WAGLEY, M.D.†

BOSTON

THERE are numerous reports in the literature of the past two years on the excellent results obtained with folic acid in the treatment of pernicious anemia, sprue and nutritional macrocytic anemias. The observations presented below suggest some limitations of the therapeutic value of folic acid‡ and indicate that its use, in the present state of knowledge, for the treatment of pernicious anemia entails a definite risk.

### MATERIAL AND OBSERVATIONS

Fourteen cases of macrocytic anemia, 10 of pernicious anemia, 1 of tropical sprue, 2 of nontropical sprue, and 1 of macrocytic anemia associated with total gastrectomy were studied.

#### Pernicious Anemia

Cases 2, 3, 4, 7 and 10 occurred in patients with classic signs and symptoms of pernicious anemia who had initially shown excellent responses to the intramuscular use of refined liver extract. They had remained asymptomatic and without hematologic or neurologic relapse for several years on doses of 1 U.S.P. unit (injectable) a day given intramuscularly at intervals of four to six weeks. To determine the effect of folic acid, liver-extract therapy was stopped. The patients were then started on the folic acid regimens indicated in Table 1. As shown in the table, 3 patients (Cases 2, 3 and 4) had neurologic relapses with diminution in the vibratory sense

in each. Two (Cases 2 and 3) were asymptomatic when the diminution of the vibratory sense was first demonstrable. However, 1 patient (Case 4) also complained of the appearance of numbness and tingling of the hands and feet associated with a sense of weakness, although no gross increase in papillary atrophy developed, the same patient began to complain of "burning" of the tongue. These relapses occurred from six to twelve months after folic acid therapy was started.

Two patients (Cases 7 and 10) have not shown neurologic relapses after nine and four months of therapy on 5 and 10 mg. of folic acid a day, respectively.

The following cases of pernicious anemia are presented in more detail because of individual variations.

**CASE 1.** A 40-year-old woman was admitted to the hospital with the chief complaint of weakness. The family and past histories were noncontributory. The present illness had begun approximately 2 years previously with transient sore tongue, easy fatigability and slowly progressive weakness. The pertinent physical findings were pallor, slight icterus, retinal hemorrhages, papillary atrophy of the tongue, a positive bilateral Babinski sign and slight diminution of the vibratory sense in the left leg. A serologic test for syphilis was negative. The red-cell count was 730,000, with a mean corpuscular volume of 134 cu. microns and a mean corpuscular hemoglobin concentration of 29 per cent. There was no free hydrochloric acid in the gastric secretions after the administration of histamine. Many megaloblasts were present in the sternal marrow. After being on 25 mg. of folic acid orally per day for 8 days the patient complained of sudden inability to void urine. Cystometric studies showed a toleration of 900 cc. of water without a voiding response. When once initiated the voiding response was well maintained. There was no residual urine. This was interpreted as indicating a sensory lesion. A marked progression in the loss of vibratory and position senses was evident at that time. The patient was immediately started on intramuscular liver-extract therapy. Seventy-six days later she was not anemic and had no difficulty in voiding. She continued to have

slightly diminished vibratory sense over the left leg and a positive bilateral Babinski sign but was otherwise asymptomatic

**CASE 5** A 31-year-old Negress had been well maintained for several months on liver extract at the rate of 1 *USP* unit (injectable) a day given intramuscularly every 4 weeks. At the beginning of this study the patient was asymptomatic.

she was asymptomatic. There was no papillary atrophy of the tongue. Neurologic examination was negative. Examination of the blood showed a red-cell count of 4,750,000. The mean corpuscular volume was 89 cu microns, and the mean corpuscular hemoglobin concentration was 31 per cent. At the end of 7 months of therapy the patient complained of occasional sore tongue and numbness in the left leg. At the end of 10 months she complained of severe numbness and

									300	Intravenously, daily for 2 days		

\*No significant change.

†This patient had undergone total gastrectomy

She was taken off liver-extract therapy for a period of 4 months. At the end of that time she noted easy fatigability. Physical examination revealed no unusual conditions. Examination of the blood showed that the red-cell count had fallen to 3,200,000, with a mean corpuscular volume of 112 cu microns and a mean corpuscular hemoglobin concentration of 31 per cent. The patient was started on 5 mg of folic acid orally a day. At the end of 5 months of therapy

tingling in the arms, hands, legs and feet. The ankle jerks were of high threshold, with brief and sluggish response. The vibratory sense was diminished over the ankles, knees and iliac crests. The hematocrit remained at 44 per cent.

**CASE 6** A 48-year-old Negress, who had been followed periodically for several years at the Johns Hopkins Hospital with the complaint of weakness, had responded well

to liver extract intramuscularly at first but after 3 years of infrequent attendance in the Outpatient Department she reappeared complaining of general weakness with numbness of the hands and feet. Physical examination showed marked pallor, slight papillary atrophy of the tongue and diminution of vibratory sense over the legs. A serologic test for syphilis was negative. Examination of the blood revealed a red-cell count of 1,410,000 with a mean corpuscular volume of 116 cu microns and a mean corpuscular hemoglobin concentration of 34 per cent. Gastric secretion disclosed no free hydrochloric acid after the administration of histamine. The patient's blood responded dramatically to daily oral doses of 30 mg of folic acid (Table 1). On the 28th day the daily dose was lowered to 10 mg. Six months after the beginning of treatment she was asymptomatic. Three months later however she returned complaining of abrupt onset of numbness and tingling in the hands and feet. She noted unsteadiness of gait and had some urgency and dribbling of urine. The tone of the adductor femoris muscles was increased. The abdominal reflexes and ankle jerks had disappeared. No plantar responses were elicited. Tactile sensation and appreciation of pinprick had markedly diminished over the legs.

CASE 8. A 56-year-old machinist was admitted to the hospital with the complaint of a sore tongue and "feeling run down." The family and past histories were noncontributory. The present illness had begun 7 months prior to admission with anorexia, sore tongue and weakness. Physical examination showed pallor, injection and atrophy of the glossal papillae and normal neurologic signs. A serologic test for syphilis was negative. Examination of the blood disclosed a red-cell count of 1,600,000 with a mean corpuscular volume of 137 cu microns and a mean corpuscular hemoglobin concentration of 31 per cent. There was no free hydrochloric acid in the gastric secretion after the administration of histamine. The sternal marrow showed numerous megaloblasts. The patient's blood revealed a good response to 20 mg of folic acid a day orally (Table 1). However after 35 days numbness and tingling of the hands and feet appeared and progressed in severity. The soreness of the tongue became extremely annoying. Occasionally the glossal surface showed tiny petechiae, and the papillae remained injected. The patient was started on liver extract intramuscularly. The soreness of the tongue, as well as the numbness and tingling of the hands and feet, disappeared by the end of 1 week.

CASE 9. A 74-year-old housekeeper had first been admitted to the hospital in 1927 with pernicious anemia. For 1 year prior to the last admission in 1945 the patient had received no treatment. For several months she had noted increasing fatigability, dyspnea, slight ankle edema, a sore tongue and numbness and tingling of the hands and feet. Physical examination showed marked pallor, marked papillary atrophy of the tongue and diminution of the vibratory sense over both legs. A serologic test for syphilis was negative. Examination of the blood disclosed a red-cell count of 1,110,000 with a mean corpuscular volume of 135 cu microns and a mean corpuscular hemoglobin concentration of 32 per cent. An occasional megaloblast was present in the peripheral blood. The patient was given intravenously 100 mg of folic acid a day, prepared according to the technique described by Darby et al.<sup>1</sup> By the end of the 1st week she felt much stronger. On the 6th day of therapy a reticulocyte peak of 42 per cent was attained (Table 1). On the 26th day the patient was changed to daily oral doses of 15 mg of folic acid. During the 10th month of such therapy numbness and tingling of the hands and feet recurred. The vibratory sense had disappeared below the costal margin and was diminished elsewhere.

## Sprue

CASE 11. A 70-year-old Porto Rican woman was admitted with the chief complaints of weakness, dizziness, vomiting and diarrhea. The patient's mother and sister had had a similar condition. The past history was noncontributory. Approximately 2½ years before admission loose, foul smelling numerous bowel movements had begun. Weight loss and sore tongue were noted. Weakness became extreme. She was given "liver injections" by a physician and improved markedly. A few months prior to admission she neglected further therapy and relapsed. Physical examina-

tion showed emaciation, pallor, injected and atrophic glossal papillae and slight generalized abdominal tenderness. Neurologic examination was negative. A serologic test for syphilis was negative. Examination of the blood revealed a red cell count of 2,640,000 with a mean corpuscular volume of 121 cu microns and a mean corpuscular hemoglobin concentration of 33 per cent. The sternal marrow showed 7 per cent megaloblasts. The stools which were pale, unformed, foul smelling and copious contained no occult blood and showed no pathogenic ova or parasites. The oral glucose tolerance and vitamin A absorption curves were flat.\* X ray studies of the gastrointestinal tract disclosed distortion of the mucosal pattern and pooling of the barium. The patient was placed on daily doses of 45 mg of folic acid orally. By the 8th day the stools were much less frequent and were well formed. A reticulocyte peak of 92 per cent was attained on the 5th day of therapy. She became quite jovial and felt much stronger. Kymographic tracings of intestinal motility before treatment and 12 days after treatment showed changes indicating less frequent and less marked peristaltic waves. A glucose tolerance test on the 17th day was normal. During the 3rd week of treatment the vitamin A absorption curve following the oral administration of 200,000 units remained quite flat, although the fasting serum vitamin A level had risen from 82 to 140 microgm per 100 cc. during therapy. On the 20th day of therapy the patient was started on liver extract intramuscularly since it was thought that she might neglect subsequent medical supervision and direction. She had developed no neurologic disturbances during folic acid therapy.

CASE 12. A 65-year-old laborer with known nontropical sprue of 4 years' duration had responded well to the intramuscular use of liver extract. After 9 months of withdrawal of liver-extract therapy the patient was admitted with the chief complaints of recurrent episodes of diarrhea, weakness and numbness and tingling of the hands and feet. Physical examination showed evidence of recent weight loss, pallor and glossal papillary atrophy, with normal neurologic signs. A serologic test for syphilis was negative. Examination of the blood disclosed a red-cell count of 2,290,000 with a mean corpuscular volume of 125 cu microns and a mean corpuscular hemoglobin concentration of 31 per cent. The two or three daily stools were well formed and had been for several days despite lack of medical therapy. The oral glucose tolerance curve was flat, but the intravenous curve was normal. Folic acid was administered in doses of 30 mg a day orally. On the 6th day of therapy a reticulocyte peak of 5 per cent was attained (Table 1). On the 21st day of therapy the vitamin A absorption curve remained flat (ranging from 38 to 54 microgm per 100 cc. in the fasting and 3 hour serum specimens) on the following day the glucose tolerance curve was normal. X ray studies of the gastrointestinal tract 3 weeks after the institution of therapy continued to show alterations compatible with the clinical diagnosis of sprue. There were no episodes of diarrhea during a 45-day observation period. The patient gained 18 pounds in weight during that time, and the red-cell count rose to 4,620,000 with a mean corpuscular volume of 97 cu microns. No neurologic disturbances developed during folic acid therapy.

CASE 13. A 50-year-old man was followed medically over a period of 10 years with nontropical sprue. The family and past histories were noncontributory. During observation the patient had bulky frothy, yellow foul-smelling stools from four to seven times or more daily despite liver-extract given intramuscularly every 4 weeks at the rate of 1 U.S.P. unit (injectable) per day. Physical examination showed evidence of weight loss, pallor, no glossal papillary atrophy and a protuberant soft abdomen, with normal neurologic signs. A serologic test for syphilis was negative. Examination of the blood revealed a red-cell count of 3,660,000 with a mean corpuscular volume of 109 cu microns and a mean corpuscular hemoglobin concentration of 31 per cent. The gastric secretion contained free acid. Folic acid in daily intravenous doses of 100 mg was administered for 6 weeks. The bowel movements remained profuse, bulky and unformed. The oral glucose tolerance curve remained flat and administration of vitamin A orally in an amount of 200,000 units caused a level of only 25 microgm per 100 cc. at the

\* Vitamin A determinations were made by Dr. H. W. Josephs.

end of 3 hours. X-ray studies of the gastrointestinal tract continued to show hypermotility and changes compatible with the diagnosis of sprue. On 45 mg of folic acid orally daily for 18 months the stools remained unformed and foul smelling and increased in number. The stool fat content remained high (42.5 per cent of the dry weight). The hematocrit did not rise. No abnormal neurologic signs or symptoms appeared.

### *Post-Gastrectomy Macrocytic Anemia*

**CASE 14** A 47-year-old Negress was admitted to the hospital with the chief complaint of inability to walk. The family history was noncontributory. The past history was of interest in that, 7 years prior to admission, the patient had been seen at another hospital complaining of abdominal cramps, anorexia and a 25-pound weight loss within a 6-month period. X-ray studies were interpreted as showing a gastric tumor mass. A total gastrectomy was performed. Microscopical sections of the gastric wall were subsequently studied by Dr. Arnold R. Rich and showed nonspecific lymphocytic infiltration. The patient remained asymptomatic and led a vigorous life until the present illness. Three months before admission the patient noted a rapid onset of numbness and tingling of the legs, associated with progressive inability to walk that became so severe 2 months later that she was confined to bed. There had been a 30-pound weight loss. Physical examination revealed evidence of recent weight loss, marked pallor and moderate papillary atrophy of the tongue. The tendon reflexes of the quadriceps femoris and semitendinosus were of very low threshold and showed brisk response. There was increased tone in the adductors of the legs and contractures of the gastrocnemius-soleus muscles. There was transient, partially sustained clonus on dorsiflexion of the left ankle. The Babinski signs were negative. The vibratory sense was absent below the iliac crests. Muscle strength was good. A serologic test for syphilis was positive. Examination of the blood revealed a red-cell count of 1,830,000, with a mean corpuscular volume of 128 cu microns and a mean corpuscular hemoglobin concentration of 30 per cent. The sternal marrow showed 19.5 per cent megaloblasts. Direct visualization at the lower end of the esophagus demonstrated an esophagojejunal anastomosis and no gastric mucosa. The patient was given 300 mg of folic acid intravenously daily for 2 days and 600 mg intravenously daily for 14 days. The neurologic status was so serious that progression or improvement in such a short time could not be evaluated accurately. The red-cell count rose 600,000, and the hemoglobin rose 2 gm per 100 cc in 16 days. The reticulocyte count reached a peak of 3.2 per cent on the 8th day of therapy. On the 17th day folic acid was stopped and liver extract was given intramuscularly (10 USP units of crude extract and 15 USP units of refined extract) daily for several days, followed by an average daily dose of 1.5 USP units (injectable) of refined liver extract given every 2 to 4 weeks. There was no second reticulocyte peak. After 6 months the patient was able to walk easily without a cane. She had no numbness or tingling. The red-cell count was 5,200,000 6 months after the beginning of liver-extract treatment.

### DISCUSSION

In the 10 cases of pernicious anemia treated with folic acid the patients who had anemia at the beginning of treatment showed very good hematologic responses. There was no hematologic relapse. Five patients had been asymptomatic while on liver-extract therapy for several years. However, 8 patients, while taking folic acid, showed neurologic disturbances of varying severity within periods ranging from eight days to twelve months. Two patients had difficulty with voiding of urine, 1 showing by cystometric study alterations suggesting a sensory lesion. Diminution in the vibratory sense and numbness and tingling in the hands and feet were the most frequent developments. One patient showed signs suggesting extensive damage to the reticulospinal

tracts. Two patients, while still asymptomatic, gave evidence of progressive diminution of the vibratory sense in the lower extremity. The onset of signs and symptoms in 2 cases was abrupt and severe. Usually, the neurologic changes appeared clinically to be most marked in the sensory as contrasted to the motor modality. Three patients had either progression or return of soreness and burning of the tongue. In 1 case this was associated with gross changes consisting of papillary injection, atrophy and petechial hemorrhages. This patient responded within a week to liver extract given intramuscularly, at the end of that time there was no soreness and no glossal petechiae.

One patient with tropical sprue showed excellent clinical and hematologic response to folic acid therapy, but of 2 patients with nontropical sprue only 1 had a remission. The other, who had not previously responded to liver extract, showed no change in the blood either on parenteral or oral dosage and no marked change clinically. No neurologic disturbances developed in the cases of sprue during folic acid therapy.

A patient with total gastrectomy of seven years' duration, associated with macrocytic anemia, severe neurologic changes and weight loss, did not show a marked reticulocytosis or clinical improvement over a sixteen-day period of intensive folic acid therapy parenterally. There was a definite though small rise in the red-cell count and hemoglobin level. Although subsequent liver extract did not cause any rapid changes there was gradual and progressive improvement over a period of several months both hematologically and neurologically.

The high incidence of pathologic neurologic signs and symptoms developing among patients with pernicious anemia who previously had been adequately controlled with liver extract indicates the inadequacy of folic acid therapy for this aspect of the disease. That these disturbances did not follow doses of folic acid that were simply too small is indicated by other observations. Spies et al.<sup>2</sup> have stated that increasing dosages to amounts of 500 mg a day have not ameliorated the progression of neurologic lesions in some cases. The abruptness and severity of neurologic relapse in an occasional case suggest the possibility of an actual deleterious effect of folic acid. In a series of 21 cases of pernicious anemia treated by Spies et al.<sup>2</sup> with doses of folic acid varying from 70 to 105 mg a week, paresthesias and unsteady gait developed in 4. The dosage was then increased to 50 and even 500 mg a day for ten to forty days without subjective or objective neurologic improvement. Nine other patients with subacute combined degeneration were then treated with folic acid. Two showed questionable improvement, whereas the remainder either became worse or did not improve. One patient revealed detectable progressive neurologic changes

after only twenty-two days of folic acid in daily oral doses of 10 mg

Hall and Watkins<sup>3</sup> have reported 14 cases of pernicious anemia in relapse treated with folic acid. Of 10 patients with paresthesias of the extremities 8 improved. However, improvement was only temporary in 4, in whom paresthesias returned two to four months after the beginning of therapy. Two patients who had not had paresthesias prior to folic acid therapy developed them five months after the institution of treatment. Castle and Berk<sup>4</sup> have observed a neurologic relapse in 1 of 10 cases of pernicious anemia treated with folic acid. The less frequent incidence in their series may have resulted from the mode of administration. Their patients were given 75 mg of folic acid intramuscularly at weekly intervals. Daily treatment was not given. Heinle and Welch<sup>5</sup> have observed an "explosive" and rapidly progressive neurologic relapse in a patient with pernicious anemia receiving folic acid therapy. Meyer<sup>6</sup> noted the development and progression of neurologic symptoms in 3 patients with pernicious anemia receiving folic acid in daily doses of 15 to 50 mg, orally, or 20 mg intramuscularly.

The high incidence of glossitis during the treatment of patients with pernicious anemia is another symbol of the inadequacy of folic acid in their therapy. One patient's main complaint was severe glossal pain. Papillary petechiae developed during treatment. Although folic acid did not improve the condition, liver extract caused marked improvement in the discomfort and the petechiae disappeared within a week. Hall and Watkins<sup>3</sup> have reported that of 7 patients with pernicious anemia sustained improvement of the glossitis occurred in only 3.

The excellent response of tropical sprue to folic acid treatment seems well established.<sup>7-9</sup> However, in a case of nontropical sprue reported above no convincing improvement occurred with either folic acid or liver-extract therapy. The response of the other patient is difficult to evaluate, since he was in partial clinical remission when therapy was begun. He had previously responded well to liver-extract treatment. Although so few observations warrant no definite conclusions, the differences in thera-

peutic effects in these 3 cases suggest that there are fundamental variants in the pathogenesis of sprue. Neurologic disturbances did not appear in any case of sprue during folic acid therapy.

#### SUMMARY

The development or recurrence of neurologic disturbances occurred in 8 of 10 cases of pernicious anemia treated with folic acid. No hematologic relapse was observed.

The development or recurrence of neurologic disturbances was occasionally abrupt and severe, as well as rapid in course. The time of appearance could not be predicted.

In 3 of 10 cases of pernicious anemia glossitis either occurred during or did not respond to folic acid therapy.

One patient with tropical sprue responded dramatically. One patient with nontropical sprue responded very well, whereas another did not show any convincing improvement on folic acid or liver-extract therapy. Neurologic disturbances did not develop in the cases of sprue during folic acid therapy.

There was a slow effect of folic acid and liver extract in a patient with macrocytic anemia following total gastrectomy.

The observations presented indicate that the use of folic acid in the present state of knowledge entails a definite risk of injury to the nervous system in pernicious anemia.

## LIPEMIA RETINALIS\*

## Report of a Case

SAMUEL STEARNS, M D,† ELI FRIEDMAN, M D,‡ MAURICE LUGITCH, M D,§ AND  
SUMNER H. HOFFMAN, M D ¶

BOSTON

**L**IPEMIA retinalis is a rare manifestation of the hyperlipemia that is commonly associated with diabetic acidosis. Since the original description by Heyl<sup>1</sup> in 1880, a total of 62 cases have been reported in diabetic and 6 in nondiabetic patients. The rarity of retinal lipemia is indicated by the experience of Joslin and his associates,<sup>2</sup> who discovered only 9 cases among 29,000 patients with glycosuria in a period of forty-eight years. However, the report of 7 patients with lipemia retinalis among 108 patients treated for diabetic acidosis at the Mayo Clinic<sup>3</sup> suggests that the condition is more frequent than was formerly believed.

The funduscopic picture of retinal lipemia is striking and pathognomonic. The vessels are flat, wide, ribbon-like and faint salmon to cream in color, with decreased or absent arteriolar reflex and with little or no distinction between arterioles and veins. The earliest changes are found at the periphery of the retina, advancing toward the disk during progression and receding with improvement. The changes, which may be transient, lasting only one or two days, usually do not disappear for a week, and may persist for even three weeks. Vision generally remains normal, despite the appearance of the retinal vessels. Three fourths of the reported cases have occurred among males and the majority of patients have been children or young adults, although the condition has been observed at the age of sixty-four years.<sup>4</sup>

The following case occurred in the youngest diabetic patient with lipemia retinalis on record.

## CASE REPORT

A 4½-year-old girl was admitted to the hospital because of a 7-week history of increasing lassitude, polyphagia, polyuria, polydipsia and weight loss, culminating in drowsiness and in the discovery of sugar and acetone in the urine 12 hours before entry. Prior to the onset of this illness, the child had been of normal height and weight for her age. There was no family history of diabetes, and the past history was not relevant.

Physical examination revealed a thin, apathetic child who neither spoke nor responded to painful stimuli. She weighed 31½ pounds. There were no skin lesions. The pupils were equal and active, and the lenses clear. The fundi, which were pale, contained striking cream-colored ribbon-like vessels, which could not be differentiated into arterioles and veins. The disks were normal. The ears, nose and throat were normal except for a strong odor of acetone on the

breath, dry mucous membranes and enlarged tonsils. There was no cervical adenopathy. The heart and lungs were normal. A firm liver edge could be felt one fingerbreadth below the right costal margin, but the abdomen was otherwise normal. Neurologic examination revealed only diminished deep tendon reflexes.

The temperature was 98.6°F by rectum, the respirations 25, and the pulse 120, the blood pressure was 110/75.

Urinalysis disclosed a +++ test for glucose and acetone, a ++ test for albuminuria and occasional leukocytes and epithelial cells in the sediment. Examination of the blood revealed a red-cell count of 4,150,000 and a white-cell count of 13,200, the smear was normal. When venous blood was placed in an oxalate bottle, the cells were noted to settle rapidly, leaving a creamy white supernatant plasma. Subsequent analysis disclosed a blood sugar of 256 mg and a nonprotein nitrogen of 21 mg per 100 cc and a carbon dioxide combining power of 19 vol per cent.

Immediately after entry, an intravenous infusion of physiologic saline solution was begun, and regular insulin was given subcutaneously at hourly intervals. By the end of the first 24 hours, the patient had received 300 units of insulin and 2900 cc. of saline solution of which 1300 cc. had also contained 5 per cent glucose. At that time the child was alert and responsive. The blood sugar was 85 mg per 100 cc., the carbon dioxide combining power was 27 vol per cent, and the urine was free of sugar and acetone. The blood cholesterol, which had not previously been determined, was 1010 mg per 100 cc. The retinal vessels were slightly pinker but still paler than normal.

In the course of the following week, the diet was gradually increased, and the insulin dosage adjusted. On the 7th hospital day, the fundi were completely normal. On the 14th day, the blood cholesterol was 313 mg per 100 cc. The liver was no longer palpable. X-ray examination of the skull and chest, a tuberculin test and urinalyses were all negative. The patient gradually gained weight and was discharged on the 23rd hospital day, when the fasting blood sugar was 94 mg and the cholesterol 321 mg per 100 cc. The 24-hour urinary glucose excretion was 14.5 gm on a diet of 165 gm of carbohydrate, 70 gm of protein and 70 gm of fat, 12 units of protamine-zinc insulin and 12 units of regular insulin injected separately constituted the daily morning insulin dosage.

## DISCUSSION

Although quantitative fat determinations were not carried out, the cholesterol level of 1010 mg per 100 cc., the creamy appearance of the plasma and the pathognomonic retinal picture established the diagnosis of lipemia retinalis in this case—the 63rd case and the youngest diabetic patient with this condition to be reported.

The rarity of such cases and the transitory nature of the retinal changes make it difficult to carry out experimental procedures that might result in an understanding of the pathogenesis of this condition. It is therefore worth while to summarize and correlate some of the observations that have already appeared in the literature.

Although lipemia retinalis has never been reported in the absence of hyperlipemia, a rise in blood fats does not in itself produce the condition. Uncon-

trolled diabetes and diabetic acidosis are frequently associated with hyperlipemia, but since 1880 only 62 cases of lipemia retinalis have been reported in diabetic patients. Furthermore, retinal lipemia has not been reported in conjunction with any of the numerous other conditions usually associated with hyperlipemia, such as starvation, asphyxia, phosphorus poisoning, pneumonia, nephritis, peritonitis and myxedema.

The conclusion that lipemia retinalis appears when blood lipids exceed 35 per cent and disappears when they decrease below 25 per cent<sup>4</sup> is not borne out by other observations. Persistence of retinal lipemia has been noted at a blood lipid level of 142 per cent,<sup>6</sup> and disappearance of the retinal changes has been reported during a rise in blood lipids from 9.15 to 10.8 per cent<sup>7</sup> and during a decrease from 21.7 to 16.3 per cent.<sup>8</sup>

Neither an elevated blood sugar nor the presence of diabetic acidosis is a necessary condition for the development of lipemia retinalis. A few cases of retinal lipemia have been reported in nondiabetic patients<sup>9-14</sup> in whom there was no evidence of acidosis. At least 2 of the diabetic patients with lipemia retinalis did not have simultaneous acidosis.<sup>15, 16</sup>

Attention has been called<sup>14</sup> to the observations of Boyd,<sup>17</sup> who found that milky serums sometimes contain normal amounts of fat whereas clear serums sometimes contain rather large amounts of fat. Visibility of the blood fats can be correlated with a relative decrease of phospholipids, so far as the total amount of natural fat, fatty acids, cholesterol and cholesterol esters is concerned.<sup>17</sup> Boyd concluded that phospholipids tend to maintain the other fat fractions in a supersaturated state in serum, when the phospholipid content of serum diminishes, lipids come out of solution as chylomicrons forming a milky emulsion. Such fat droplets have been demonstrated in lipemia retinalis in blood smears,<sup>18</sup> in capillary loops by the Lombard technique,<sup>7</sup> in muscle biopsy for frozen section and Sudan III stain<sup>19</sup> and in autopsy material.<sup>20</sup> The size of some of these droplets has been estimated as varying from that of a red cell to approximately 20 microns in diameter.<sup>7</sup> In normal serum, however, chylomicrons vary from 35 millimicrons to 1 micron in diameter.<sup>21</sup>

A relative decrease in phospholipids has indeed been observed in diabetic acidosis, in which Man and Peters<sup>22</sup> found that serum fatty acids rose much more than either the serum cholesterol or the phospholipids. In 2 cases of lipemia retinalis Marble and Smith<sup>23</sup> observed that the greatest increase in the blood fats had occurred in the fatty acid fraction, the next greatest in the cholesterol, and the least in the phospholipid fraction. A decrease in organic acid soluble phosphorus of the blood cells occurs with diabetic acidosis,<sup>24</sup> indicating a depletion of labile phosphorus reserves.<sup>25</sup> Significantly, although the blood chloride, sugar and carbon

dioxide combining power promptly return to normal and phosphaturia promptly ceases with adequate treatment, the organic acid soluble phosphorus of the blood cells does not become normal for a week, at which time phosphaturia reappears.<sup>26</sup>

It seems probable, therefore, that depletion of phosphate reserves plays an important role in the pathogenesis of lipemia retinalis. A review of the literature reveals, in every completely reported case, a long preliminary period of uncontrolled diabetes, frequently with much weight loss and malnutrition. Although specific details are not presented in most cases of lipemia retinalis in nondiabetic patients, there is some reason to believe that the periodic vomiting, marasmus, alcoholic gastritis or hepatosplenomegaly variously reported in these cases had some bearing on the nutrition of the patients.

### SUMMARY AND CONCLUSIONS

The 63rd and youngest patient with diabetic lipemia retinalis is reported. Lipemia retinalis is a retinal manifestation of hyperlipemia with a changed state of blood lipids in the direction of formation of larger than normal chylomicrons. Whatever the cause of the hyperlipemia, there is some evidence that the changed state of the blood fat results from depletion of phospholipids. This in turn may be due to a long period of malnutrition with, in diabetes mellitus, a specific loss of phosphates in the urine.

## MEDICAL PROGRESS

## THE TOXEMIAS OF PREGNANCY

BENJAMIN TENNEY, JR., M.D.\*

BOSTON

**T**HIS review of the toxemias of pregnancy considers the four syndromes involving primarily hypertension with or without albumin in the urine. The first two are essential hypertension and renal disease, they may or may not be influenced by pregnancy. Secondly, pre-eclamptic toxemia and eclampsia are discussed. These conditions are the result of the pregnancy itself. It should be stated in the beginning that clinical diagnosis and classification are frequently difficult and often impossible. If a patient is first seen after she has become pregnant, the presence of hypertension or albuminuria or both offers a very confused picture. There are many leads suggesting the fundamental disease, which may or may not be present, but, in many cases, the final diagnosis cannot be confirmed until months after the patient has been delivered. Even then, there may be doubt regarding the actual condition involved.

It is also extremely important to realize that in all cases in which there is basic renal or vascular disease, true toxemia of pregnancy may be superimposed on the original condition. In fact, any pregnant woman who has had renal or vascular disease previous to pregnancy has a much greater chance of developing true toxemia than one with a healthy renal vascular system. For instance, a woman with chronic nephritis may become extremely ill in pregnancy from the chronic nephritis, but she may become more acutely and rapidly ill from the development of a superimposed pre-eclamptic toxemia. Frequently, it is extremely difficult to recognize when a previous renal vascular disease develops into pre-eclamptic toxemia. Fortunately the treatment is in a large degree essentially the same, but the prognosis and the speed with which dangerous symptoms develop vary in the different conditions. A woman with chronic nephritis can carry a much greater hypertension with reasonable safety than one with a true pre-eclamptic toxemia. A patient with essential hypertension may go through pregnancy uneventfully with a hypertension that in a pre-eclamptic might suddenly develop into eclampsia. Therefore, the best clinical judgment and all available laboratory facilities must be used to distinguish between the different entities. Dexter and Weiss<sup>1</sup> emphasize the importance of the distinction in the following statement: "Organs

weakened by pre-existing hypertensive disease are more susceptible to the strain imposed upon them by toxemia than are organs previously healthy, there being a greater tendency to cardiac decompensation, renal insufficiency, and more severe retinal lesions."

## ESSENTIAL HYPERTENSION

Essential hypertension in pregnancy is a hypertension that existed previous to pregnancy. There are cases in which, although no hypertension has been recorded before pregnancy, the disease or tendency exists and shows up early in pregnancy. It is reasonable to state that any hypertension developing in the first half of pregnancy is not pre-eclamptic toxemia. Without any signs of permanent kidney damage, this rise in blood pressure is presumably due to essential hypertension. If a patient develops a blood pressure of 140 systolic, 90 diastolic, before or during the first half of pregnancy, without signs of kidney damage, the case must be classed as essential hypertension. In this hypertension the systolic pressure frequently rises to 180. In mild cases there is little else to show, and the patient feels well. There is usually no albumin in the urine. These patients will generally do well. They must be watched more carefully than the normal patient, and they must be more careful of their diet and activities, owing to the greater danger of developing toxemia.

The etiology of essential hypertension is unknown, as is that of pre-eclamptic toxemia. The similarity of the two conditions is marked, since in both cases, the primary hypertension is due to spasm of the arterioles. In essential hypertension the long-continued progress of the disease causes hypertrophy of the arteriolar muscle and finally degeneration of that muscle with fibrous displacement. The duration of pre-eclamptic toxemia is sufficiently limited so that this final permanent damage to the arterioles does not take place. However, if the toxemia is allowed to continue too long, permanent damage to the arterioles takes place. In the benign type of hypertension, permanent kidney damage is a late complication. In the malignant type, renal insufficiency develops early, and this is the chief danger. There is probably a marked hereditary tendency in essential hypertension. Certain people have a marked constitutional abnormality, which may lead to the

\*Associate professor of obstetrics, Boston University School of Medicine, assistant visiting surgeon in obstetrics and gynecology, Boston City Hospital; assistant obstetrician, Massachusetts General Hospital.

development of hypertension. The cold pressor test is of interest, in that the great majority of essential hypertensive patients give positive reactions. Also, a large number of otherwise normal people who react to this test will eventually develop hypertension.

The work of Grollman<sup>2</sup> in essential hypertension suggests a relation to pre-eclamptic toxemia. He states that the kidney — by some humoral, if not by an incretory, mechanism — may be concerned in the pathogenesis of hypertensive cardiovascular disease as commonly observed in man, and as produced with ease in the experimental animal. The fact that hypertension follows manipulations of the kidney, as well as the high incidence of hypertension observed in the human being with kidney disease, leaves little doubt that the experimental disease, as well as many cases of clinical hypertension, is secondary to dysfunction of the kidney.

According to Grollman<sup>2</sup> the removal of the injured kidney, either in man or in animals, does not lower the blood pressure. If one kidney is injured and the other is removed, there is an immediate rise in the pressure. In contrast to much previous work, he believes that the normal kidney produces an incretory substance that regulates the normal blood pressure, and that the removal of normal kidney tissue, or damage to it, removes this control over blood pressure and thus results in hypertension.

The work of Smithwick<sup>3</sup> in lumbodorsal sympathectomy throws an interesting light on the relation of essential hypertension to pre-eclamptic toxemia. The marked lowering of hypertension following this operation frequently allows patients to proceed uneventfully through pregnancy. These patients, with the hypertension previous to operation, would be serious risks for pregnancy. One patient in particular, who with a previous pregnancy developed severe cerebral and visual disturbances, had to have the pregnancy terminated at seven months. After a sympathectomy, she went uneventfully through a normal full-term pregnancy. In spite of this operation some of these patients develop pre-eclamptic toxemia. In a series of 13 cases reported by Newell and Smithwick,<sup>4</sup> 3 patients developed definite signs of pre-eclamptic toxemia, 1 had a premature separation of the placenta, and in 1, labor had to be induced before term.

The prognosis of essential hypertension of the benign type in pregnancy is good. The majority of these patients have an uneventful pregnancy. The incidence of pre-eclamptic toxemia is higher in them than in normal women, and they should be watched more carefully. Particularly, they should have sufficient rest, a careful diet and a minimum weight gain. Any increase in hypertension, or the appearance of albumin in the urine, indicates the probability of the development of pre-eclamptic toxemia. Dexter and Weiss<sup>1</sup> believe that women with pre-pregnant hypertension (essential hypertension) pass

through pregnancy without damage if they do not develop pre-eclamptic toxemia. They consider an added risk to the fetus to exist in these cases. Sharkey and Hess<sup>5</sup> state that pregnancy causes no significant change in essential hypertension. They do not regard the hypertension as having any effect on the infant. In their own series, these patients did as well as the normal women.

In a series of 301 pregnant patients, Chesley, Annitto and Jarvis<sup>6</sup> report 218 cases classifiable as hypertensive toxemia. The outstanding hazard of pregnancy is the superimposition of toxemia, which occurred in about 30 per cent. The incidence of eclampsia in these hypertensive patients was ten times that in all patients, whereas the incidence of pre-eclampsia increased seven times. The gross fetal mortality was 34 per cent. The majority of hypertensive women apparently are not jeopardized by pregnancy; two thirds of these patients escaped superimposed toxemia. In patients who did not have toxemia, 30 per cent had greater hypertension at follow-up study than when originally observed. The authors conclude that repeated pregnancies are not harmful to the hypertensive woman. The pregnancy itself is hazardous should toxemia occur. If the toxemia causes damage, the prompt interruption of a hypertensive pregnancy, at the first sign of developing toxemia, should benefit the patient.

Essential hypertension of the malignant type is a more serious disease. Without pregnancy, the prognosis of these patients is poor. The added strain of pregnancy is apt to precipitate serious complications. Pregnancy should be definitely avoided in such cases.

#### RENAL DISEASE

The differentiation of the various forms of kidney disease is somewhat of an academic problem. The separate types — glomerular, arteriosclerotic, nephritic and pyelonephritic — offer great difficulty in differential diagnosis. It is vital that the clinician recognize permanent kidney disease. All types of kidney disease are alike, in that they respond poorly to pregnancy. Any damaged kidney has a lowered reserve. The additional load of pregnancy may be too much for this lack of reserve. Pregnancy may cause renal failure. Patients with damaged kidneys may develop a superimposed pre-eclamptic toxemia. The incidence of toxemia in these patients is much higher than that in normal persons. It is often extremely difficult to judge when a nephritis may show renal failure in pregnancy, but the addition of toxemia will make the condition more acute and rapid in progress. It is also essential to realize that patients may have renal disease from childhood infections, or other causes, of which they are entirely unaware. Often, it is the first pregnancy that brings the kidney disease to light. A negative past history obtained from a patient does not rule out the possibility of renal damage.

The symptoms of renal disease appear early in pregnancy. The milder forms may not appear until later. It is the mild forms that are most frequently confused with pre-eclampsic toxemia. A patient who appears during the first months of pregnancy with hypertension, albuminuria and edema should be studied for the presence of nephritis. The systolic blood pressure is variable, sometimes being over 200, usually it is lower. Extremely high blood pressures with no cerebral symptoms are characteristic of chronic nephritis rather than pre-eclampsia. The urine will show albumin, and frequently casts and red cells, in contrast to pre-eclampsia. The blood pressure does not fall immediately after delivery as in pre-eclampsia but continues for months and often permanently. The albumin may persist after delivery. Nitrogen retention may be present in the severe cases as shown by a high blood nonprotein nitrogen. In pre-eclampsia there is no nitrogen retention. According to Stander<sup>7</sup> a high nonprotein nitrogen is pathognomonic of kidney disease. This is not found in pre-eclampsia unless eclampsia develops. According to Stander a study of the renal-function tests is essential. In pre-eclampsia the kidney function is normal, whereas in kidney disease a decreased function is often found. Stander recommends the fifteen-minute phenol-sulfonephthalein, the urea clearance and the dilution and concentration tests. He believes that the dilution and concentration test is the most sensitive to slight degrees of kidney damage. Examination of the eye grounds frequently shows the presence of retinal hemorrhage and albuminuric retinitis, which is absent in pre-eclampsia.

The prognosis of renal disease in pregnancy is poor. Stander gives the average maternal mortality occurring within ten years, after the disease has been recognized, as 40 per cent. Each pregnancy increases the kidney damage and undoubtedly shortens the life of the patient. The prognosis for the babies is extremely poor. DeLee<sup>8</sup> gives the fetal mortality as 66 per cent. Many women with renal disease abort. In many others the infant dies during labor and delivery. Commonly the babies die in utero during the last month of pregnancy. The prognosis for the fetus is so poor that induction of labor when the fetus is viable is frequently the best procedure. The large placental infarcts that are often found in chronic nephritis, involving from one quarter to one half of the placenta, threaten the life of the fetus during the later months and during labor itself. Premature separation of the placenta occurs in chronic nephritis, although not so commonly as in the pre-eclampsic toxemias.

A woman with proved renal disease should not become pregnant. Her chances of obtaining a living healthy baby are about one in three. The pregnancy will shorten her life, owing to increased kidney damage. There is also the risk of the pregnancy itself with the large incidence of pre-eclampsic

toxemia, as well as other accidents of pregnancy, which these patients do not stand well. Should a patient be seen when she is already pregnant and the renal damage is slight, an attempt may be made to carry her through the pregnancy. The dangers should be explained to her and her husband. She should be carefully watched, given a proper diet and liquid intake, and sufficient rest, and immediately hospitalized if any sign of renal failure appears. In the severe cases, the prognosis for the baby is so poor, and the danger to the mother so great, that abortion should be performed immediately.

### PRE-ECLAMPTIC TOXEMIA

The following definition by Dexter and Weiss<sup>1</sup> is as specific a description of this condition as can be made.

Toxemia of pregnancy (pre-eclampsia and eclampsia) is a humoral and vascular disorder characterized by the appearance, in the second half of pregnancy, of an excess of edema, an elevation of the blood pressure or an increase in the amount of albumin in the urine, or both, above that present before or in the early weeks of pregnancy, and a rapid decrease of edema, lowering of blood pressure, and of the amount of albumin in the urine soon after delivery.

These authors continue with the following statements. Toxemia of pregnancy differs from non-pregnant hypertension chiefly in its relation to water retention. The hypertension of early toxemia is not of renal origin. The toxemia syndrome occurs in mothers with pre-pregnant hypertensive disease as well as in those without. The two most important predisposing factors to development of toxemia are pre-pregnant hypertension (in one third of the cases) and generalized edema (in 85 per cent).

According to Dieckmann<sup>9</sup> the development of pre-eclampsic toxemia is influenced by diet, habits and climate. A hot, wet climate is most favorable for the development of eclampsia. He states that the Mohammedans in India develop more eclampsia than the Hindus or Christians owing to the difference in the amount of meat in the diet. The elimination of sodium chloride, proteins and fats lowers the incidence of severe pre-eclampsia and eclampsia, but not of mild pre-eclampsia.

Eastman<sup>10</sup> gives the statistics of 2418 pre-eclampsic patients over a period of twenty years. In this series there were 92 cases of eclampsia, or an incidence of 3.8 per cent. In eclampsia the maternal mortality was 7.6 per cent, and the fetal mortality 21.7 per cent. The maternal mortality in pre-eclampsia was 0.2 per cent, and the fetal mortality was 6.8 per cent. In twenty years the incidence of eclampsia resulting from pre-eclampsia was reduced from 14.2 to 2.3 per cent. This reduction was due to the earlier recognition of pre-eclampsia and better treatment of that condition.

Cosgrove and Chesley<sup>11</sup> report a series of 1625 cases of pre-eclampsic toxemia. The maternal mortality in this series was 1 per cent. The inci-

dence of premature separation of the placenta was 38 per cent, and that of eclampsia was 5.5 per cent. The total fetal mortality was 171 per cent. The authors state that prophylaxis cannot prevent the actual occurrence of toxemia.

The first appearance of hypertension or albuminuria or both with a sudden gain in weight in the last trimester in pregnancy must be taken to mean the development of pre-eclampsic toxemia. If there is a sudden gain in weight, without the development of hypertension or albuminuria, the possibility of impending toxemia must be considered. A sudden gain in weight in a woman who has been on a reasonable diet usually indicates the presence of visible or invisible edema or of fluid retention.

Dexter and Weiss<sup>1</sup> found generalized edema in 64 per cent of otherwise normal pregnant women. The physical characteristics, distribution, etiology, time of appearance and post-partum disappearance were identical with those of women with toxemia. In 100 patients with edema, the history of previous menstrual headaches and premenstrual edema was twice as frequent as that in patients without edema. Frequently, the appearance of generalized edema was followed shortly by the appearance of toxemia. The incidence of toxemia in women with generalized edema was far greater than that in those without. They were unable to explain the presence of edema by hydrostatic pressure, increased capillary permeability, hypoproteinemia or anemia. A humoral etiology was suspected.

Dieckmann<sup>2</sup> explains the formation of edema by decreased colloid osmotic pressure of serum proteins, increased permeability of capillary walls, and increased capillary pressure. The venous pressure in the leg veins is increased in normal pregnancy, causing a retardation in the absorption of fluid. The capillaries are more permeable. There is a delayed excretion of water and sodium chloride. Edema of the ankles in pregnancy is normal, but other edema is not. Hidden edema is best shown by weight gain, and is often the earliest symptom of toxemia. There is a rapid increase of the incidence of toxemia in excessive weight gain.

The appearance of edema in otherwise normal pregnant women is such a common occurrence that it is frequently not regarded with sufficient gravity. The increased incidence of toxemia following fluid retention is well known. Edema can be partially controlled and sometimes eliminated by proper diet and fluid intake. The fluid intake of any woman developing edema should be restricted. A pregnant woman can be comfortable on as little as 1 liter of fluid in twenty-four hours. The relation of sodium intake to fluid retention is important. It has been shown that the elimination of sodium from the diet often lowers the blood pressure. If salt and sodium compounds are removed from the diet and fluids are limited, most women will excrete a large amount

of the retained fluid and lose a corresponding amount of weight.

Hypertension in pre-eclampsic toxemia (a blood pressure above 140 systolic, 90 diastolic) appears before albumin in the urine in the majority of cases. Hypertension or albuminuria, or both, does not appear before the last trimester of pregnancy. A pregnant woman who has passed uneventfully through the first six months of pregnancy and then develops hypertension presumably has pre-eclampsic toxemia. The blood pressure in this disease runs at a lower level than that in chronic nephritis and essential hypertension. A systolic pressure of 160 in toxemia is a dangerous level. Eclampsia develops at this and at slightly higher levels. This hypertension is due to arteriolar spasm and is not the result of primary kidney disease. This is true only from a clinical standpoint, for it is possible that kidney damage could be demonstrated by more sensitive kidney-function tests than are now available. The level of hypertension must be watched very closely. A steady and rapid rise in blood pressure, even though not great in extent, is an indication of the severe or fulminating type of toxemia, in which eclampsia rapidly develops. In the milder forms of pre-eclampsia, the blood pressure rises slowly and will hold a given level for weeks, or even fall, under the proper medical treatment. When the blood pressure continues to rise in spite of medical treatment the pregnancy should be terminated.

In pre-eclampsia, albumin is the only abnormal finding in the urine. The albumin may appear at first as a very slight trace or may appear rapidly in large amounts. The amount of albumin present has some relation to the severity of the disease but is not so accurate a guide as the hypertension. The small number of cases in which albumin appears first are of the milder form. The presence of casts or blood cells suggests kidney disease rather than true toxemia. In the fulminating type of pre-eclampsic toxemia and in eclampsia, blood cells and casts may appear, owing to secondary damage to the kidney from the toxic process.

As pre-eclampsia progresses, further symptoms are likely to develop. These symptoms usually indicate a more serious and advanced stage of the disease. The cerebral symptoms most often start with headache, which may develop further into dizziness and drowsiness. Visual symptoms, such as diplopia, scotoma and blurred vision, are of serious prognosis. Nausea and vomiting with epigastric pain may be the precursor of eclampsia. When pre-eclampsia is recognized in its earliest stages and responds to proper treatment, these symptoms should not develop, their appearance indicates that the disease is progressing unfavorably.

The etiology of pre-eclampsia is unknown, in spite of much study and investigation. There are many predisposing factors and some fundamental findings

in this disease. Dexter and Weiss,<sup>1</sup> who state that here is some evidence that toxemic patients are more sensitive to the effect of posterior pituitary substance than others, were unable to cause permanent hypertension in rabbits with large and repeated doses of posterior pituitary extract. There were no significant histologic changes in these rabbits. Extracts of placentas from patients with high blood pressure were injected into rabbits without causing any pressor effects, and no such effects were obtained with amniotic fluid. Renin could not be demonstrated in the placentas of patients with increased blood pressure. There was no rise in blood pressure in babies delivered of toxemic mothers. It was concluded that if a pressor substance is present in the mother, it does not cross the placenta. In 16 cases with death of the fetus in utero, 11 mothers showed no improvement of the toxemia until after delivery. These cases indicate that the placenta was the important factor in toxemia.

Dieckmann<sup>9</sup> states that Pituitrin causes a marked rise in blood pressure and suppression of urine in pre-eclampsia. This effect was not observed in hypertensive and renal disease. The thyroid gland is enlarged in the majority of pregnant women. A deficiency in thyroid causes an increase in tissue fluids that contain more proteins. The retention of extracellular fluid may be tremendous. Hypothyroidism produces hypercholesteremia in rabbits, with severe endarteritis of the placental arteries. Colvin and Bartholomew<sup>12</sup> found no cases of toxemia in patients in early pregnancy with a basal metabolic rate of +10 per cent or above. There was an increasing incidence of toxemia as the basal metabolic rate fell. In patients with a rate of -10 per cent or below, there was an incidence of 50 per cent. Many believe that thyroid extract is a good prophylactic against pre-eclampsia.

Smith and Smith<sup>13</sup> have found high levels of chorionic gonadotropin and low estrogenic activity in the blood and urine of toxemic patients. There is also a deficiency of progesterone, the same titer occurs normally just before and during labor. This hormone change occurred weeks before the development of toxemia. The authors believe that fortnightly measurement of the serum gonadotropic hormone, from the fifth month on, will reveal an abnormal rise, eight to ten weeks before the disease becomes clinically apparent, in about 80 per cent of cases. Premature deterioration of placental steroids may be prevented by large doses of diethylstilbestrol. Large doses of estrogenic substance will also increase the production of progesterone. Sufficient clinical work has not been done fully to evaluate this treatment for pre-eclamptic toxemia. Large doses of estrogenic substance after the signs of toxemia have appeared have proved of little value. If a sufficient number of cases were studied and treated early in pregnancy, before the onset of toxemia, the results

could be correlated against the incidence of toxemia in a control group.

More recently Smith<sup>14</sup> has become interested in a toxin isolated from normal menstrual blood. He is impressed by the resemblance of certain physiologic findings in menstruation and toxemia. He mentions retention of water, the decrease of serum diastase, the increased uterine irritability, the systemic disease, which he states is like that of premenstrual and early menstruating endometrium, and, finally, the amelioration of the disease when the uterus is emptied and the removal of the decidua is under way. He has been unable to demonstrate the presence of menstrual toxin in pre-eclampsia or eclampsia. A protective pseudoglobulin has been developed for the treatment of pre-eclamptic toxemia. There was a fall in the blood pressure, as well as a decline in the amount of albumin in the urine, in the patients treated. This work is of great interest because, in many ways, the toxin has the properties necessary for toxemia. However, this toxin has not as yet produced toxemia in animals or human beings, and the clinical results of treatment are still too few and indefinite for any final conclusions.

Cosgrove and Chesley<sup>16</sup> state that definite functional and structural changes in the vascular system, particularly the capillaries and arterioles, are the most universal pathologic tendency in pre-eclampsia. Hertig<sup>16</sup> remarks that toxemia of pregnancy—in all its manifestations, including eclampsia, toxic separation, cortical necrosis, pituitary necrosis and placental degenerations—is part of the same fundamental process. A pathological classification of the separation of the normally implanted placenta fixes the blame for the mortality in this condition, almost, if not wholly, on the toxic variety. Certain placental degeneration that occasionally occurs in all the groups of the American classification, including so-called "minimal toxemia," may cause the death of the fetus in utero. He stresses the fact that some babies due to die in utero from this cause may be saved by prompt action when fetal growth has ceased. The smaller the infant, the more certain it is that placental degeneration exists.

Tenney and Parker,<sup>17, 18</sup> in a study of the histopathology of the placenta in pre-eclamptic toxemia and eclampsia, found a placental lesion characteristic of this disease. The lesion consists primarily of a premature aging of the placenta, which takes place in the syncytium of the small villus buds. A normal full-term placenta will show from 10 to 50 per cent degenerated buds. A count of one hundred to two hundred villus buds should be made for an accurate determination. In pre-eclampsia and eclampsia this degeneration involves from 50 to 100 per cent of the syncytial buds. It is extremely important that the actual age of the placenta be taken into account. Syncytial degeneration in the normal placenta does not begin before the eighth month and, as stated

above, does not reach over 50 per cent at term. Therefore, in a seven-month placenta, there should normally be no syncytial degeneration. The finding of a moderate amount (about 25 per cent) of syncytial degeneration in a seven-month placenta would be indicative of pre-eclamptic toxemia, whereas in a full-term placenta, there would have to be over 50 per cent to indicate toxemia. In essential hypertension, uncomplicated by toxemia and renal disease, this typical degeneration is not found. The amount of syncytial degeneration observed in toxemia is relative to the severity of the disease. In 100 cases of pre-eclamptic toxemia, pronounced placental lesions were noted in 60 per cent. In 90 per cent of these cases albuminuria was present. In the other 40 per cent, which showed less pronounced lesions, albuminuria was present in less than half. This suggests that placental damage begins before clinical symptoms appear. If the syncytium is regarded as similar in function to the glomerular epithelium of the kidney, the destruction of this epithelium, together with circulatory congestion, may explain the high fetal mortality in this condition.

The renal changes in toxemia are best described by Bell.<sup>19</sup> The glomeruli are slightly enlarged. The lumens of their capillaries are narrowed, and sometimes completely closed, so that they contain but few erythrocytes. The decrease of the capillary lumen is caused mainly by thickening of the capillary basement membrane. The increase in the endothelial cells is variable. Dexter and Weiss,<sup>1</sup> in a study of 25 cases of fatal eclampsia that came to autopsy, found the combination of microscopical changes observed in the kidneys specific and characteristic for toxemia in all cases. The lesions were primarily degenerative, and the term "glomerulonephrosis" seemed most suitable. These changes are sometimes noted in mild pre-eclampsia.

The typical liver lesion of eclampsia was found in only 50 per cent of autopsies at the Mallory Institute of Pathology. This lesion consists of hemorrhagic necrosis of the peripheral portion of the liver lobules. When this lesion is found, it is definitely specific for eclampsia. In this connection the work of Ingerslev and Teilum<sup>20</sup> is of interest. They performed aspiration biopsies on the livers of normal pregnant women and on those with pre-eclamptic toxemia and eclampsia. There were no changes in the livers of the former and no histologic or chemical grounds to maintain the concept of a pregnancy liver. In pre-eclampsia the authors also found no change. In eclampsia peripheral hemorrhagic necrosis was observed in 50 per cent of cases. The liver damage in the patients with toxemia appears to have been a terminal result, not a cause, of severe disease.

Dieckmann<sup>8</sup> describes extensive cerebral hemorrhage in 15 to 20 per cent of autopsies in deaths from eclampsia.

The physiochemical changes in the blood and urine of women with pre-eclamptic toxemia have been thoroughly studied by many investigators. Unfortunately, there is no physiochemical test that is pathognomonic of this disease. The nonprotein nitrogen of the blood is not high in pre-eclampsia. It is only in the later stages and in eclampsia that a rise is found. Stander<sup>7</sup> describes a high blood ureic acid which is an important aid in the differentiation of pre-eclamptic toxemia, but it is not a consistent finding. Dieckmann<sup>8</sup> describes a blood concentration in severe pre-eclampsia and eclampsia, but this is not found in the mild cases.

Eastman<sup>10</sup> gives four objectives in the treatment of pre-eclamptic toxemia: prevention of convulsions, prevention of residual hypertension, delivery with minimal trauma and yet in a manner that will not handicap the patient in future pregnancies, and delivery of a living child.

Prophylaxis is the first and most important treatment. Every pregnant woman should be under medical care from the time that she first knows she is pregnant. She should be on a high-protein diet including plenty of meat, fish, eggs and milk. She should have a low-fat and low-carbohydrate intake. Salt and other sodium compounds should be limited to a minimum. Fluids should be allowed in amounts necessary for comfort, but excessive fluid intake should be avoided. The weight should be carefully followed, the weight gain for the entire pregnancy should be limited to 20 pounds. If the patient becomes overweight, she should try to reduce. In cases of excessive weight gain, the patients should be put on a diet of 1200 calories. If the patient does not co-operate and obtain an immediate weight loss, she should be hospitalized, and the weight reduced under supervision. She should be given iron and vitamins during the entire pregnancy and should have sufficient rest and a moderate amount of exercise. Proper and regular bowel elimination is important.

If hypertension or albuminuria, or both, develops in the last trimester of pregnancy, the patient should first be treated by medical means. She should be confined to bed and put on a high-protein, fat-free diet. All salt and sodium must be eliminated from the diet. If there is visible edema or an increase in weight, 1 liter of fluid daily should be prescribed, and one good cathartic and sufficient laxative for a daily bowel movement should be given. A sedative is helpful. Frequently, a patient improves and can be up and about on a restricted regime.

If the patient does not respond to the treatment outlined above she must be hospitalized. The same regime is continued under hospital care, with the possible addition of intravenous hypertonic glucose. Blood-pressure readings must be taken frequently, a careful record kept of the fluid intake and output, and daily catheterized specimens exam-

ed in the laboratory. If, in spite of treatment, the blood pressure continues to rise and the albuminuria increases, termination of the pregnancy is indicated. The method used to terminate the pregnancy must depend on the severity of the disease and the condition of the patient. In the acute, fulminating type of toxemia occurring in primiparas, cesarean section is usually the method of choice. Even in some multiparas with acute exacerbation of symptoms and an unfavorable cervix, cesarean section may be indicated. In milder cases and even in severe cases of multiparas in which the cervix is favorable, rupture of the membranes and delivery from below may be the best procedure. However, each case must be judged by itself, and the attending obstetrician should take the whole situation into consideration before making his decision.

### ECLAMPSIA

Eclampsia is the final stage of an unchecked pre-eclampsia. Many cases of pre-eclampsia are not sufficiently severe to develop into eclampsia, but many other cases do, if not properly treated. Eclampsia is the development of convulsions or coma, or both, following pre-eclampsia. Not all cases of coma or convulsions in pregnancy are due to eclampsia. Among the causes of convulsions that must be differentiated from eclampsia are epilepsy, hysteria and diabetes. Also, various cerebral lesions must be ruled out. The convulsions of eclampsia may appear before, during or after labor. Typically, a patient has a series of convulsions separated by periods of lethargy. Accompanying the convulsions is marked hypertension and albuminuria. Casts—hyaline, epithelial and granular—may appear in the urine. There is a marked reduction in the output of urine and sometimes complete suppression. DeLee<sup>8</sup> gives the maternal mortality of eclampsia as 13 per cent, with a fetal mortality of 40 per cent.

The treatment of eclampsia should be preventive. The uterus should be emptied before the convulsions appear. Once the convulsions have appeared, the treatment is primarily conservative. On the basis of the original Stroganoff treatment, sedation and rest are the primary objectives. The patient should be put in a quiet and dimly lighted room. The eyes should be covered, and the ears blocked with cotton. She should be well sedated with morphine and chloral hydrate. Chloroform is still used to control the convulsions. Magnesium sulfate may be given intravenously in a 20 per cent solution. Hypertonic glucose may be administered intravenously to stimulate kidney excretion. Veratrine is recommended by Kellogg.<sup>21</sup> Willson<sup>22</sup> states that the administration of veratrine causes a marked suppression of urine in pre-eclampsia. Dieckmann<sup>9</sup> warns of the danger of vascular collapse from this drug.

The treatment of the disease is the fundamental problem in eclampsia, and no attempt at delivery should be made during the convulsive stage. Cesarean section is definitely contraindicated. Frequently, labor begins, and delivery is normal. In other cases, when the convulsions are under control, labor may be induced, and the patient allowed to progress through labor. Rupture of the membranes is the simplest and surest way of induction, and the use of the bag is not recommended. The patient often shows some improvement after the rupture of the membranes. The labor should be allowed to proceed at its own speed, and no interference should be considered until the cervix is fully dilated. Frequent complications of eclampsia are anuria, pulmonary edema and sepsis.

The end results of pre-eclampsia and eclampsia show permanent damage in many cases. According to Kellogg<sup>21</sup> the residual lesion from the former is hypertension, which was found in 50 per cent of cases. After eclampsia, hypertension was present in 60 per cent. Glomerulonephritis did not occur in any patient as the result of eclampsia. The older the patient, the greater the parity, the higher the blood pressure during pregnancy and the longer the duration of the illness, the greater the liability to the ultimate occurrence of hypertension.

Dexter and Weiss<sup>1</sup> believe that hypertension follows toxemia of pregnancy in 25 per cent of patients who have had a normal blood pressure before pregnancy, and an elevation in the percentage of women who have had hypertension before pregnancy. The occurrence of sustained post-partum hypertension depends more on the duration than on the severity of the toxemia. Sustained hypertensive vascular disease may be initiated by toxemia of pregnancy.

Reid and Teel<sup>23, 24</sup> report that in 235 cases previously diagnosed as mild pre-eclampsia, six months to three years after delivery, no patients had renal impairment. In 21 per cent the systolic pressure was over 150. Of 89 patients with hypertension before pregnancy, 44 per cent had a higher blood pressure six months to three years after delivery than when first seen.

Browne and Dodds<sup>25</sup> report 400 toxemic patients studied six to twelve years after delivery. Fifty-one per cent had hypertension. They found, as Kellogg did, that older patients with greater parity, higher blood pressure and longer duration of illness were more likely to develop hypertension. There were no cases of glomerulonephritis as a result of toxemia. Sixty per cent of the patients had hypertension after eclampsia. The authors suggest that patients who develop residual hypertension after pre-eclamptic toxemia and eclampsia have a familial tendency to the disease, which pregnancy has merely revealed. The onset of pregnancy hastens the disease, which sets in at an earlier period than it would otherwise have done.

## SUMMARY

Essential hypertension of the benign type is not seriously influenced by pregnancy. There is a greater incidence of pre-eclamptic toxemia in these patients than in normal pregnant women. A superimposed toxemia is a serious danger.

Pregnancy is a dangerous complication of renal disease, resulting in increased kidney damage. Superimposed toxemia increases this damage. Pregnancy should not be permitted in severe renal disease.

Pre-eclamptic toxemia is best treated by proper prophylaxis. Excessive weight gain is a predisposing cause. If the toxemia does not respond to medical treatment, the uterus should be emptied before convulsions develop.

Eclampsia should be treated conservatively.

Permanent hypertension after toxemia has a definite relation to the length of time the disease persists, as well as to its severity.

### CASE 34011

#### PRESENTATION OF CASE

A seventy-eight-year-old man entered the hospital complaining of an ache in the abdomen of three weeks' duration.

For six weeks he had noted ankle edema. Soon he developed swelling of the abdomen, anorexia, mild abdominal distress, exertional dyspnea, and watery, black stools four times a day. In this period he lost 8 pounds. Previously his health had been excellent. He denied orthopnea, chest pain, cough, jaundice or

excessive alcohol intake. He admitted taking a glass of wine with meals. For six months the patient had suffered from incontinence, frequency, nocturia, weak stream and difficulty initiating the stream.

Physical examination revealed a well developed but emaciated, elderly man in no distress. No jaundice was noted. A Grade I aortic systolic murmur was heard. Abdominal examination showed ascites, a liver edge palpable 3 cm. below the costal margin and slightly tender, bilateral inguinal hernias, hemorrhoids and a prostate one and a half times the normal size. There was +++ pitting edema of the ankles and lower legs.

The temperature, pulse and respirations were normal. The blood pressure was 175 systolic, 85 diastolic.

Examination of the blood disclosed a red-cell count of 5,900,000, with 16.5 gm. of hemoglobin, and a white-cell count of 8400, with a normal blood smear. The urine contained no albumin, sugar or bile, and had a specific gravity of 1.020. Two stools were guaiac negative. The total protein was 5.96 gm. per 100 cc., with an albumin-globulin ratio of 1.41. The nonprotein nitrogen was 30 mg. and the cholesterol 156 mg. per 100 cc., the esters being 85 mg. per 100 cc. The time was 27 seconds (normal, 17, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 1419, 1420, 1421, 1422, 1423, 1424, 1425, 1426, 1427, 1428, 1429, 1430, 1431, 1432, 1433, 1434, 1435, 1436, 1437, 1438, 1439, 1440, 1441, 1442, 1443, 1444, 1445, 1446, 1447, 1448, 1449, 1450, 1451, 1452, 1453, 1454, 1455, 1456, 1457, 1458, 1459, 1460, 1461, 1462, 1463, 1464, 1465, 1466, 1467, 1468, 1469, 1470, 1471, 1472, 1473, 1474, 1475, 1476, 1477, 1478, 1479, 1480, 1481, 1482, 1483, 1484, 1485, 1486, 1487, 1488, 1489, 1490, 1491, 1492, 1493, 1494, 1495, 1496, 1497, 1498, 1499, 1500, 1501, 1502, 1503, 1504, 1505, 1506, 1507, 1508, 1509, 1510, 1511, 1512, 1513, 1514, 1515, 1516, 1517, 1518, 1519, 1520, 1521, 1522, 1523, 1524, 1525, 1526, 1527, 1528, 1529, 1530, 1531, 1532, 1533, 1534, 1535, 1536, 1537, 1538, 1539, 1540, 1541, 1542, 1543, 1544, 1545, 1546, 1547, 1548, 1549, 1550, 1551, 1552, 1553, 1554, 1555, 1556, 1557, 1558, 1559, 1560, 1561, 1562, 1563, 1564, 1565, 1566, 1567, 1568, 1569, 1570, 1571, 1572, 1573, 1574, 1575, 1576, 1577, 1578, 1579, 1580, 1581, 1582, 1583, 1584, 1585, 1586, 1587, 1588, 1589, 1590, 1591, 1592, 1593, 1594, 1595, 1596, 1597, 1598, 1599, 1600, 1601, 1602, 1603, 1604, 1605, 1606, 1607, 1608, 1609, 1610, 1611, 1612, 1613, 1614, 1615, 1616, 1617, 1618, 1619, 1620, 1621, 1622, 1623, 1624, 1625, 1626, 1627, 1628, 1629, 1630, 1631, 1632, 1633, 1634, 1635, 1636, 1637, 1638, 1639, 1640, 1641, 1642, 1643, 1644, 1645, 1646, 1647, 1648, 1649, 1650, 1651, 1652, 1653, 1654, 1655, 1656, 1657, 1658, 1659, 1660, 1661, 1662, 1663, 1664, 1665, 1666, 1667, 1668, 1669, 1670, 1671, 1672, 1673, 1674, 1675, 1676, 1677, 1678, 1679, 1680, 1681, 1682, 1683, 1684, 1685, 1686, 1687, 1688, 1689, 1690, 1691, 1692, 1693, 1694, 1695, 1696, 1697, 1698, 1699, 1700, 1701, 1702, 1703, 1704, 1705, 1706, 1707, 1708, 1709, 1710, 1711, 1712, 1713, 1714, 1715, 1716, 1717, 1718, 1719, 1720, 1721, 1722,

cephalin-flocculation test + in twenty-four and +++ in forty-eight hours

A barium-enema examination was negative. Chest films showed collapse of the right upper lobe, which contained multiple small cavities. There was old pleuritis at the right base and apex. The trachea and upper mediastinal structures were displaced to the right.

Paracentesis produced 3230 cc of bloody fluid with 430,000 red cells and 150 white cells per cubic millimeter and a specific gravity of 1.010. No tumor cells or tubercle bacilli were found in the ascitic fluid.

Cystoscopy showed no cause for the urinary symptoms except a slightly enlarged prostate.

The patient became quite jaundiced, and the ascites recurred. On the fifteenth day bleeding into the skin occurred, and 200 cc of blood was aspirated from the mouth. He died the following morning.

#### DIFFERENTIAL DIAGNOSIS

DR MYLES P. BAKER: We are dealing with an elderly patient with ascites and ankle edema of relatively short duration (three to six weeks) and a noteworthy absence of symptoms, except for those attributable to prostatic hypertrophy. There was a history suggestive of bleeding from the upper gastrointestinal tract. The important negative findings on physical examination seem to me to be the absence of evidence of congestive heart failure, the absence of any abnormal physical findings, particularly over the right upper lobe, the absence of a palpable spleen or spider angiomas, and also the lack of a really large liver. The liver edge was said to be palpable 3 cm below the right costal margin, but that is only about two fingerbreadths, if that, and we do not know where the upper border of the liver was. Possibly, the finding represents a low liver rather than a large one. There is no note on rectal examination regarding whether any firm mass was palpable in the rectal shelf. Presumably it was not, or it would have been mentioned. But that is an important finding in an elderly person with ascites.

The laboratory studies revealed certain important features. First of all, there was no anemia—or surprisingly little for a man in whom liver disease is suspected. There was no element of renal insufficiency, which is significant in a man who had been having urinary symptoms that made him uncomfortable rather than ill. There was no bile in the urine, which tallies with the finding of no detectable icterus. We have no evidence on examination for bleeding into the gastrointestinal tract. The serum protein of 5.96 gm per 100 cc is barely below the normal range, and the serum albumin can be calculated as  $\pm 3.5$  gm per 100 cc, which is slightly below the normal range but not so low as one would expect to be one of the chief causes of a large accumulation of ascitic fluid. The globulin of 2.4 gm

per 100 cc is at the upper limits of normal and not so high as one would expect in the usual case of cirrhosis of the liver with ascites. The normal blood cholesterol levels are about what one would expect, and I do not quite see why the test was done in the first place. There was no significant decrease in the esterified portion, as one sees with acute liver-cell damage. The prolonged prothrombin time is important, but it was not within the danger level that causes hemorrhage. Finally, the cephalin-flocculation test of +++ in forty-eight hours is consistent with liver-cell damage. The one test that I should expect that the house officers would have recourse to, the bromsulfalein-excretion test, apparently was not done. The finding of bloody ascitic fluid, of course, sticks out in this protocol like a sore thumb. It has always been and is still a very rare finding in cirrhosis of the liver and immediately directs one's attention toward the possibility of a cancerous process involving the peritoneum. X-ray examinations were subsequently done, probably with this in mind. A barium enema revealed no evidence of cancer in the cecum, sigmoid or rectum. X-ray examination of the chest revealed an abnormal finding, a collapsed right lower lobe with multiple small cavities, which I think I shall ask Dr Wyman to describe.

DR STANLEY M. WYMAN: The collapsed right upper lobe lies in this location at the apex, with what appears to be thickened pleura over the apex. Multiple small areas of decreased density are present that may represent dilated bronchi scattered throughout this rather shrunken lobe. The trachea is deflected considerably toward the right. The right leaf of the diaphragm is moderately elevated, and there is what may be a small amount of fluid or thickened pleura in the costophrenic angle. The heart shadow is retracted a little toward the right, with a prominent left ventricle, a tortuous aorta and some calcification, which is all in keeping with the hypertension. The lung fields, except for the right upper lobe, show no definite localized disease. I can trace the bronchi rather well in both lung fields. I cannot entirely exclude obstruction of the right upper-lobe bronchus, however. A barium enema is described, but I can only find incomplete films of that examination. A gastrointestinal series was apparently done, although we have no report of it, but it may be of help to Dr Baker. The esophagus can be seen very fragmentarily, and there is no definite evidence of esophageal varices. The stomach appears to be within normal limits. I believe that there is probably an enlarged liver and possibly a large spleen.

DR BAKER: Do you consider these areas of diminished density in the collapsed lobe compatible with dilated bronchi rather than cavities?

DR WYMAN: Yes, or they could be small bronchiectatic cavities.

DR BAKER In a further search for possible sites of carcinoma, a cystoscopy was done, and apparently carcinoma of the prostate excluded. The patient went on to die in two weeks, a short course of seven weeks' illness in all, with evidence terminally of bleeding in the gastrointestinal tract and the skin, and deepening jaundice—a picture that we consider compatible with a cholemic death. Against the diagnosis of cirrhosis of the liver, again, are the bloody ascitic fluid, the serum albumin level of 3.5 gm per 100 cc in the presence of ascites, the absence of anemia, the absence of splenomegaly to be found in probably two thirds of such cases of cirrhosis and ascites and the absence of collateral circulation found in 50 per cent of such cases and of spider nevi. The patient was old for cirrhosis.

The question arises whether the findings in the chest by x-ray examination are compatible with a diagnosis of bronchiogenic carcinoma. I cannot rule out the presence of a bronchostenotic lesion involving the right upper-lobe bronchus. With such a lesion I would expect more evidence of active infection distal to the tumor. However, it is interesting to remember that in bronchiogenic tumors the first symptoms may be those of metastases, distant metastases, rather than mere chest pain and blood-streaked sputum. Bronchiogenic carcinoma frequently metastasizes by way of the blood stream and involves the liver in about 35 per cent and the peritoneum in 4 to 5 per cent, and the abdominal lymph nodes in a third of the autopsy cases. The possibility of such an origin of carcinoma must therefore be borne in mind in this case. I have never seen such a situation, however,—ascites as the presenting symptom with bronchiogenic carcinoma,—possible though it may be, and I could find no reference to it in the literature. I am inclined to look upon the findings that Dr Wyman has demonstrated in the chest x-ray film as an old story in an elderly man, due probably to inflammatory disease involving the upper-lobe bronchus with atelectasis, representing an inactive process.

The question of a primary hepatoma arises in this patient, who presented grossly bloody ascites, which is a common finding in the presence of this rather rare tumor, probably in two out of three malignant hepatomas such grossly bloody ascites is found. We have very little evidence for the presence of cirrhosis of the liver, which is frequently associated with primary hepatomas, and I think that the absence of such an antecedent history of cirrhosis and of a large, firm, hard liver are rather important points against the diagnosis of hepatoma. It is a rare tumor. Moreover, we have no evidence of tumor elevating the right leaf of the diaphragm—a finding that I have seen in cases of hepatoma. In considering a possible site of origin for what I take to be metastatic carcinoma involving the parenchyma of the liver and peritoneum, I come then by exclusion to carcinoma of the body of the

pancreas. The patient had none of the characteristic backache, left sided or midline, that such persons with carcinoma of the body of the pancreas have. This tumor frequently involves the peritoneal surface as well as the liver and gives rise to progressive swelling of the abdomen as the initial symptom, closely followed by edema of the ankles, jaundice and the clinical picture presented in this case. Perhaps chiefly because I have seen it do so, I shall choose it as the most likely diagnostic probability in this man who presented bloody ascites as the outstanding abnormality and who gave, for reasons noted above, no grounds for the diagnosis of cirrhosis of the liver.

DR CHESTER M. JONES Is it not true that in the lower film it would be impossible to state that the liver or spleen was enlarged because there is so much fluid and homogeneous density?

DR WYMAN Yes

#### CLINICAL DIAGNOSIS

Peritoneal carcinomatosis

DR BAKER'S DIAGNOSIS

Carcinoma of body of pancreas

#### ANATOMICAL DIAGNOSES

*Hepatoma, with extension into portal and hepatic veins*

*Portal cirrhosis of liver, inactive*

*Bronchiectasis, right upper lobe*

*Benign prostatic hypertrophy*

*Arteriosclerosis, generalized*

#### PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY I think that this case is a very blid one from the diagnostic point of view. The diagnosis was established a day or two before death by peritoneoscopy, but we believed that there would be no fun in discussing it if we gave the results of the peritoneoscopic biopsy of the liver. It showed the characteristic picture of hepatoma. At autopsy the right lobe of the liver was completely replaced by tumor, which had invaded extensively both the portal and the hepatic venous systems. This is characteristic of primary liver-cell carcinomas. There were no distant metastases. The spleen was not enlarged, weighing only 170 gm. There were no esophageal varices. There was, however, in the left lobe of the liver, evidence of an old burnt-out cirrhosis, such as is almost invariably found in patients who develop hepatoma. We have had only 1 case in this laboratory of primary liver-cell carcinoma not associated with cirrhosis. That was in a ninety-five-year-old woman. Dr Kernahan, what is your experience in this regard?

DR JAMES W. KERNAHAN We have just gone over our cases of carcinoma of the liver at the Mayo Clinic and found 75 per cent of the hepatomas associated with cirrhosis. Twenty-five per cent were not, but those were usually in children.

DR. MALLORY Cholangiomas in general are less frequently combined with cirrhosis than the hepatomas

Two other findings of possible importance were a bronchiectasis in the right upper lobe and a moderate hypertrophy of the prostate

DR. BAKER Do you often find pain in the right upper quadrant in patients with hepatoma?

DR. MALLORY One does, but one also finds pain in the right upper quadrant in patients with cirrhosis who have no tumor. There is no explanation for the pain whatsoever

## CASE 34012

### PRESENTATION OF CASE

A nineteen-year-old boy was admitted to the hospital because of difficulty in urination.

Three months before entry he began to notice an "itch" in the anus that gradually changed to a dull ache "inside," above the anus and to the left. This pain was worse on bending over. It finally became so severe that he was unable to lie on his back. One month later, while at work, he had a sudden episode of dizziness and "pins-and-needles" sensation all over. This passed off in an hour but left him weak, and he did not wholly recover for two or three weeks. Eight days before entry he was unable to urinate although the bladder felt distended. He had to be catheterized. Two days later he again was unable to void and had to be catheterized. This time he had severe back pain as well. In the last five days before admission he had difficulty in urination, relieved somewhat by Sitz baths. The back pain was intermittent and associated particularly with retention. He had mild constipation and a weight loss from 135 to 126 pounds in the three-month period. There was no history of frequency, nocturia, stones or venereal disease, no paresthesias of the legs and no disorder of gait.

Physical examination revealed a well developed, nervous, apprehensive boy. He had bilateral, small, soft, palpable, anterior and posterior cervical lymph nodes. There was a left lumbar scoliosis. On rectal examination there was a hard, fixed, irregularly rounded mass about 2 cm in diameter at the junction of the sacrum and coccyx, to the right of the midline. It was questionably tender. A complete neurologic examination was negative, except that the ankle jerk was less active on the left side.

The temperature was 97°F, the pulse 90, and the respirations 20. The blood pressure was 115 systolic, 60 diastolic.

The white-cell count was 10,000, with 80 per cent neutrophils. The red-cell count was 4,570,000. The fasting blood sugar was within normal limits, and a blood Hinton test and a routine urine examination were negative. The cerebrospinal fluid was acellular, and the protein was 36 mg per 100 cc.

An intravenous pyelogram showed normal kidneys, with prompt excretion of the dye on both sides. The bladder was large and emptied incompletely. There was no definite abnormality of the pelvis. There was questionable loss of trabeculation of the right distal sacral segments, although this area was partially obscured by bowel contents. A myelogram showed a free flow of Pantopaque from the ninth dorsal body to the cul-de-sac, without evidence of defect. A barium enema showed no intrinsic disease or displacement of the rectum or sigmoid. No mechanical obstruction was seen by cystoscopy or panendoscopy. X-ray examination of the chest was negative.

While in the hospital the patient was treated with tidal drainage of the bladder and sulfadiazine. He had a few episodes of "stabbing pains" just to the left of the anus, radiating anteriorly through the perineum. These were associated with a constant grimace, and he held himself rigid on the left side.

An operation was performed on the fourteenth hospital day.

### DIFFERENTIAL DIAGNOSIS

DR. ROY E. MABREY This patient presented a history of intermittent pain in the low back extending into the perineum. He also had difficulty in urination. The onset was gradual, and the symptoms increased in severity.

The itch noticed in the anus may have resulted from irritation of a nerve, or it may have been that the patient's attention was drawn to this area. The type of pain characterized by a dull, intermittent ache could have resulted from pressure due to inflammation or to neoplasm.

The episode of dizziness with "pins-and-needles" sensation may have been due to a reflex reaction with a concomitant fall in blood pressure.

The mechanism of emptying the bladder became more and more disturbed. Eight days before admission and again two days later the patient had to be catheterized. There is no note of how much urine was obtained, but analysis was normal when he entered the hospital. An intravenous pyelogram showed no evidence of hydronephrosis, and there was enlargement of the bladder with incomplete emptying. Obstruction to the outflow, such as that due to stricture, stone or an enlarged prostate, would have caused spasm of the bladder and given rise to considerable pain. The atonic nature of the bladder, or the dysuria, points to some involvement of its nerve supply.

Neurologic examination revealed no abnormality, except that the ankle jerk was less active on the left than on the right. There were no sensory changes or disorder of gait. A lumbar puncture revealed normal fluid, but no mention was made of the dynamics. A myelogram was normal, however. These findings tend to eliminate an intrathecal lesion. The change in bowel habit with constipation

was not accompanied by diarrhea, bleeding or tenesmus. It may have been due to restricted food intake and reduced activity.

Physical examination disclosed soft lymph nodes in the neck. The axillae and groins are not mentioned. Examination of the blood showed a white-cell count of 10,000, with 80 per cent neutrophils. This is within normal limits but might point toward an inflammatory process. Other studies, including the sedimentation rate, calcium, phosphorus and alkaline phosphatase might have been of some help.

On rectal examination there was a hard, fixed, irregularly rounded mass about 2 cm in diameter at the junction of the sacrum and coccyx. The problem is to determine the nature of this fixed mass, on the assumption that it could account for all the symptoms.

In discussing the possibilities, I should like to list four general headings: congenital, traumatic, infectious and neoplastic.

Spina bifida, the most common of the congenital lesions in this region, would manifest itself at an earlier date and a defect should be noted by x-ray examination. A cyst, such as a dermoid or a teratoma, which often contains teeth or bone, would also show on the x-ray film.

There was no history of injury, and one severe enough to cause these symptoms would have caused other signs.

A perirectal abscess occurs above the levator ani muscles and is quite rare. Also, the patient is likely to have chills and fever with a high white-cell count. Osteomyelitis would give more constitutional reaction, with a high white-cell count. Tuberculosis in this area is rare without widespread involvement. The negative blood Hinton test probably rules out syphilis.

In my opinion the mass palpable on rectal examination was neoplastic in origin. It is not likely that it arose in the rectal wall. There was no ulceration of the mucosa, which would have been accompanied by bleeding and tenesmus. Any ulceration could have been detected with a sigmoidoscope, although barium studies might not have outlined it. A neurogenic tumor has to be considered and cannot be ruled out. Since the tumor arose in the vicinity of the sacrum, primary bone tumors have to be thought of. Although Ewing sarcoma has a predilection for the shaft of long bones and half the cases occur before the age of fifteen years, it may occur in the sacrum and at another age. It is likely to be accompanied by elevation of temperature, and x-ray examination usually shows new bone being deposited in layers. Osteogenic sarcoma may occur in any bone, but it is found most often in the long bones. The greatest incidence is at the age of twenty, and the pain is usually constant; the x-ray findings are more definite than they were in this case. A chondroma or chondrosarcoma is a

possibility. Metastatic disease is not likely to produce a single projecting lesion such as this.

There are two tumors left to be considered that are not too infrequent in this area: chordoma and benign giant-cell tumor. Chordoma arises from remnants of the fetal notochord. Its growth is very slow, and pain is the first symptom. A study of 150 cases reported in 1935 revealed that no patient with a chordoma in the sacrococcygeal region sought medical advice in less than four months after onset.\* The average age of the patients was fifty years, although 6 cases occurred between twenty and thirty years. Considerable destruction of bone had taken place before the patient consulted a physician.

Giant-cell tumor is usually slowly growing. The presenting symptom is pain, which is intermittent in character. The greatest incidence of occurrence is between the ages of fifteen and twenty-five. Destruction and regeneration of bone give a "soap bubble" roentgenogram.

The presence of intermittent ache and dull pain of three months' duration in a boy of nineteen, with no elevation of temperature, point to a neoplastic process. The interference with bladder function indicates that the growth occurred in proximity of the nerves of the bladder. In the absence of good x-ray films, which are usually very characteristic, I shall put giant-cell tumor of the sacrum as my first choice.

#### CLINICAL DIAGNOSIS

Chondrosarcoma of sacrum

DR. MABREY'S DIAGNOSIS

Giant-cell tumor of sacrum

#### ANATOMICAL DIAGNOSIS

Ewing sarcoma of sacrum

#### PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: This patient was seen by many consultants, and the consensus was that he had a sacrococcygeal tumor, with chondrosarcoma leading the list. It was not considered advisable to attempt a biopsy through the rectum. The lower half of the sacrum and the entire coccyx were excised en bloc by Dr. W. J. Mixer. When received in the Pathology Laboratory, the specimen showed replacement of a portion of the sacrum by reddish-gray tissue, which on microscopical examination proved to be an Ewing sarcoma.

Although there was no gross evidence of residual disease at operation, tumor was found in the soft tissues microscopically. The patient was therefore given 6000 r of x-ray therapy, 1500 kilovolts over a 15-by-15-cm. field being given during a period of six weeks. When seen two months later, he already had pulmonary metastases.

\*Mabrey R. E. Chordoma: study of 150 cases. *Am. J. Surg.*

accepted as a matter of course among industrial workers, there can be no surprise that young women of high caliber and intelligence are reluctant to go through a period of intensive training to prepare themselves as nurses. All solutions to the problem, therefore, depend essentially on the fact that the nursing profession must be made more attractive.

Thus, physicians can do much to influence qualified young women in their choice to enter this most vital profession, and efforts on the part of women's auxiliaries can be equally effective. But nurses must first be accorded the recognition and benefits commensurate with their professional status, certainly, they are justified in demanding the rights taken for granted by even unskilled workers — better pay for fewer hours of work, social security, sick leave, vacation pay and adjustment for night and overtime work. Suggestions of substituting practical nurses for registered professional nurses to take over the major part of ordinary bedside care<sup>2</sup> and for greater utilization of nurse's aides offer some hope for a solution of the problem, although such proposals appear to underestimate the danger of nursing care of inferior quality at a time when the public is demanding the highest standards in all forms of medical care. Finally, Congress must be persuaded to continue the exemption, inaugurated during the war years and permitting registration of nurses at the age of twenty, to the requirement of a minimum age of eighteen years set by the Board of Registration of Nurses for admission to nursing schools. But even girls who graduate from high school at the age of seventeen could not be blamed for seeking professions offering better pay and better working conditions than those offered by a nursing career.

Physicians and their wives are urged to make every possible contribution to the campaign of the Student Nurse Recruitment Committee. The medical profession and hospital administrations are also urged to co-operate by exerting every effort to obtain for nurses their proper recognition and economic stability.

## LIQUIDATION OF THE EMERGENCY MATERNITY AND INFANT CARE PROGRAM

A NOTICE elsewhere in this issue of the *Journal* calls attention to the liquidation of the Emergency Maternity and Infant Care Program in the United States. In Massachusetts there are many outstanding physicians' bills, some dating back to the beginning of the program. It is important that all outstanding medical bills be submitted immediately. The expanded staff necessary to carry this program is now being contracted because of the cessation of administrative funds, therefore, it will become increasingly difficult, and will take a longer time, for approval and payment of bills. It is to the physician's own interest to render his bills as soon as possible.

### ROBERT N. NYE MEMORIAL FUND

The American Cancer Society, Incorporated (Massachusetts Division), announces that the Robert N. Nye Memorial Fund is in excess of \$2385.

### MASSACHUSETTS MEDICAL SOCIETY DEATHS

**CURTIS** — Charles L. Curtis, M.D., of Salem, died on December 11. He was in his sixty-second year.

Dr. Curtis received his degree from Bowdoin Medical College in 1909. He was for many years senior member of the surgical staff at the Salem Hospital, and was a fellow of the American College of Surgeons and the American Medical Association and a member of the New England Surgical Society.

A daughter, two sons and several grandchildren survive.

**GREENWOOD** — Arthur M. Greenwood, M.D., of Boston, died on December 14. He was in his seventy-first year.

Dr. Greenwood received his degree from Harvard Medical School in 1902. He was formerly a member of the staffs of the Massachusetts General, New England Deaconess and Palmer Memorial hospitals. He was a member of the New England Dermatological Society, American Dermatological Association and American Academy of Dermatology and Syphilology and was a fellow of the American Medical Association.

His widow and two stepsons survive.

### MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

#### LIQUIDATION OF EMERGENCY MATERNITY AND INFANT CARE PROGRAM

Physicians who have outstanding bills for pediatric and obstetric care given to Massachusetts mothers and children under the Emergency Mater-

nity and Infant Care Program are urged to submit these bills for payment, immediately, since the program is now in the process of liquidation.

A separate bill and a statement of services rendered must be submitted for each patient for whom compensation has not been received. If necessary, additional copies of the required blank forms that must be completely filled out by the physician — "Physician's Statement of Obstetric Services Rendered" or the "Physician's Statement of Pediatric Services Rendered" — may be obtained from the Division of Maternal and Child Health, 73 Tremont Street, Boston. The bill must be presented on the physician's regular, printed statement form.

## STATE PLAN FOR THE ADMINISTRATION OF HOSPITAL SURVEY AND CONSTRUCTION ACT

The State Plan for the administration of Public Law 725 (Hospital Survey and Construction Act) has been approved by the State Advisory Council and the Public Health Council of the Massachusetts Department of Public Health and, following a public meeting on November 12 in Boston, by the Surgeon General of the United States Public Health Service.

In the Massachusetts Plan, existing general hospitals were distributed among seventy service areas. The most recent survey of hospital beds in Massachusetts indicates that there are 18,224 general-hospital beds, 1,100 beds for patients with chronic diseases, 3,604 beds for patients with tuberculosis and 21,102 beds for mental patients. In accordance with the federal formula as given in Public Law 725, the number of beds needed according to the categories mentioned above is, respectively, 23,829, 9,136, 4,408 and 22,840.

A priority schedule based primarily on the percentages of need met by existing facilities was established, and all general hospital construction will take place in accordance with this schedule. Top rank in the list was given to seven hospital areas within the Commonwealth — namely, Athol, Needham, Medford, Northbridge, Woburn, Milford and Ipswich. It is expected that within the first year of the program it will be possible to make two or three grants among the applicants having a Group A priority.

An allotment will also be designated for the construction of hospital units for chronic diseases. The metropolitan areas of the Commonwealth, including Boston, Springfield, Worcester and Pittsfield, will have first priority in this category. Finally, 20 per cent of the total allotment for the first year will be allocated for the construction of health centers.

## COMMUNICABLE DISEASES IN MASSACHUSETTS FOR NOVEMBER 1947

DISEASES	RÉSUMÉ		
	NOVEMBER 1947	NOVEMBER 1946	SEVEN YEAR MEDIAN
Chaserooid	5	2	2*
Chicken pox	753	770	1025

Undulant fever	3	5	4†
Whooping cough	648	598	661

\*Three-year median

†Five-year median

### COMMENT

Diseases with incidence above the seven year median are diphtheria, dog bite, German measles, salmonellosis and pulmonary tuberculosis.

Diseases below the seven year median are chicken pox, malaria, measles, meningococcal meningitis, mumps, lobar pneumonia, poliomyelitis and scarlet fever.

Poliomyelitis dropped to less than one third of the prevalence of November, 1946, the peak having occurred nearly a month earlier this year than last.

Although diphtheria did not maintain the sharp upward trend of October, the seasonal increase is certain to continue with a peak some time in December, January or February.

Measles is at the lowest prevalence for November since 1906, and chicken pox at the lowest since 1931.

### GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from: Boston, 10, Chelsea, 1, Dedham, 1, Everett, 2, Revere, 2, Somerville, 1, Westminister, 1, total, 18.

Dysentery, bacillary, was reported from: Salem, 3, Swampscott, 1, Waltham, 3, Worcester, 8, Wrentham, 6; total, 21.

Malaria was reported from: Everett, 1, Haverhill, 1, Lynn, 1, Malden, 1; Worcester, 1, total, 5.

Meningitis, meningococcal, was reported from: Brookfield, 1, Cambridge, 1, Hingham, 1, Montague, 1, Quincy, 1, total, 5.

Meningitis, Pfeiffer bacillus was reported from: Cambridge, 1, Holyoke, 1, Leominster, 1, total, 3.

Meningitis, pneumococcal was reported from: Boston, 1, Cambridge, 1, Everett, 1, Quincy, 1, total, 4.

Meningitis, staphylococcal, was reported from: Chelsea, 1, total, 1.

Meningitis, undetermined, was reported from: Agawam, 1, Chicopee, 1, Haverhill, 1, Holden, 1, Holyoke, 1, Hopedale, 1, Worcester, 1, total, 7.

Poliomyelitis was reported from: Agawam, 1, Brookline, 2, Dighton, 1, Easthampton, 1, Gloucester, 1, Ipswich, 1, Lynnfield, 1, Malden, 1, Newton, 1, Milford, 1, Salem, 2, Somerville, 1, Wrentham, 1, total, 15.

Salmonellosis was reported from: Ipswich, 1, Lynn, 1, Malden, 1, New Bedford, 1, Norwood, 1, Peabody, 1, Worcester, 2, total, 8.

Septic sore throat was reported from: Amesbury, 1, Boston, 4, Cambridge, 1, Greenfield, 1, Montague, 1, Warren, 1, total, 9.

Tetanus was reported from: Great Barrington, 1, total, 1. Triebniosis was reported from: Lawrence, 1, Lenox, 4, Lowell, 1, Pittsfield, 1, total, 7.

Typhoid fever was reported from: Boston, 1, total, 1.

Undulant fever was reported from: Avon, 1; Boston, 1, Dalton, 1, total, 3.

## MISCELLANY

### UNFILLED VACANCIES IN HEALTH DEPARTMENTS

Unfilled professional vacancies in state and local health departments of twelve States, totaling 590 more than in 1945, were disclosed recently when the Committee on Training of Public Health Personnel, United States Public Health Service, Federal Security Agency, announced the results of a spot survey made last spring. The Committee conducted the survey in April, 1947, as a follow-up of a compilation made in July, 1945, when 38 state and 930 local health departments reported a total of 2595 vacancies in nineteen categories of full-time positions and 2000 positions being held for persons in the armed services. Although incomplete information was supplied by eight of the twelve states queried last spring, a total of 1847 unfilled jobs were reported in the same nineteen categories for which the twelve states recorded 1257 vacancies in July, 1945. Replies from these states indicated that the impact of medical men returning from military duty had not yet been felt. In thirteen of the nineteen types of positions, vacancies reported in 1947 were greater than those in July, 1945. Prominent totals among unfilled positions in the twelve States checked last April were health officers, 117 (55 in 1945); medical officers, 186 (101 in 1945); graduate nurses, 940 (654 in 1945), and sanitary and public-health engineers, 81 (36 in 1945). The states included in the spot survey were California, Colorado, Georgia, Illinois, Kentucky, Louisiana, Massachusetts, Michigan, Minnesota, New York (exclusive of New York City), North Carolina and Texas.

### ASSOCIATION OF STATE AND TERRITORIAL HEALTH OFFICERS

At the annual meeting of the Association of State and Territorial Health Officers, held recently in Washington, D. C., the following officers of the Association were elected: president, Dr. Vlado A. Gettung, of Massachusetts; vice-president, Dr. R. L. Cleere, of Colorado, and secretary-treasurer, Dr. L. E. Burney, of Indiana. The Executive Committee members for 1948 include Drs. Gettung and L. E. Burney and Dr. R. R. Cross, of Illinois, Dr. P. E. Blackerby, of Kentucky, and Dr. F. C. Beelman, of Kansas.

### UNITED STATES PUBLIC HEALTH SERVICE RESEARCH FELLOWSHIPS

Research fellowships for the support of research workers in the medical and related sciences have been made available by the United States Public Health Service. Three types of fellowships are awarded. A predoctorate research fellowship, carrying yearly stipends of \$1200 for successful applicants without dependents and \$1600 for those with dependents, in addition to tuition fees, which are paid by the United States Public Health Service, is available to qualified applicants with a Bachelor's degree who wish to conduct research at the Bachelor level and to medical students who, having completed one or two years of medical school, wish to spend additional time in a basic science (such as biochemistry, physiology and physics) before completing their studies toward the M.D. degree. A predoctorate research fellowship, carrying yearly stipends of \$1600 for successful applicants without dependents and \$2000 for those with dependents, in addition to tuition fees, is available to qualified applicants with a Master's degree who wish to conduct research at the Master level and to medical students who, having completed one or two years of medical school, wish to spend additional time in a basic science before completing their studies toward the M.D. degree. A postdoctorate research fellowship, carrying yearly stipends of \$3,000 and \$3,600, respectively, for doctors without and those with dependents, is available to qualified applicants with a Doctor's degree in medical or related fields, an increase of \$300 each year being granted to fellows who are reappointed. And a special research fellowship, which does not carry a set stipend but is determined in the individual case, is available to applicants who qualify

for a postdoctorate fellowship and, in addition have demonstrated outstanding ability or who possess specialized training for a specific problem.

The fellowships are awarded for one-year periods and may be renewed. Except in unusual circumstances, postdoctorate fellows are not reappointed for a third year. Applications are acted upon and awards made at intervals of approximately three months.

Application forms and further information may be obtained from the Division of Research Grants and Fellowships, National Institute of Health, Bethesda 14, Maryland.

## CORRESPONDENCE

### COMMENTS ON FOLIC ACID

*To the Editor* It was with considerable interest that I read your editorial entitled "Folic Acid" in the February 6 issue of the *Journal*. Since at the time I had been using the vitamin for over a year and had no less than 75 patients under treatment, I was especially impressed by your statement that "folic acid as a practical therapeutic agent does not, however, directly provide 'new hope for anemics,'" and that the possible benefit of the "oral therapy" might lead to "neglect of therapy," which is a definite disadvantage.

I have tried, therefore, to restrain myself from the exaggerated optimism and enthusiasm that often accompany the introduction of a new therapeutic agent and have been carefully watching the results with an unprejudiced mind for over two years.

Just now, when our series of sprue patients treated with folic acid is over 100, I have read your second editorial, entitled "A Warning Regarding the Use of Folic Acid," which appeared in the November 6 issue of the *Journal*—the same issue in which Sargent's review, "Folic Acid, Pteroylglutamic acid and related substances," is presented.

Although Sargent finishes his paper with the statement that "because a full clinical trial has not been made, it is too early to venture an opinion on the final place of this nutrient in therapeutics," you end the editorial by stating "Consequently the use of folic acid as a therapeutic agent appears to offer no new benefit but only risk to the patient."

In pernicious anemia, the risk appears to be the alarming incidence of reported neurologic relapses or progression of pre-existing neurologic lesions, sometimes with an explosive onset and spread. Two cases of sprue have been noted by Ross in the United States in which neurologic lesions occurred during folic acid therapy. Of three possible mechanisms of folic acid action on the neurologic disturbances, you mention that the nutrient "may actually exert a positively deleterious influence on the nervous system."

We agree with Sargent that a more exact definition of the clinical entities being studied is essential for the just appreciation of the real effect of therapy. We have seen cases treated for sprue, both here and abroad, that did not fulfill the most important criteria for diagnosis. Two years ago, at one of the clinics of the postgraduate courses sponsored by the American College of Physicians, in a Boston hospital, we were shown the case of an aged woman physician suffering from sprue, who failed to respond to the oral administration of folic acid. The diagnosis was based on steatorrhea and hypochromic anemia.

We have not yet observed the development of neurologic disturbances in sprue during folic acid therapy. The only patient showing typical signs of combined-system disease as pointed out by Suárez, Spies and Suárez ("The Use of Folic Acid," *Ann Int Med* 26:643, 1947) had the condition before the vitamin was started, the question whether it was a case of sprue or of pernicious anemia is still unsettled.

In going over our cases, we can say that the hematologic response of sprue patients to folic acid is as good as that observed with liver extract, but the improvement in their gastrointestinal manifestations is more striking. A number of patients who had been maintained on parenteral liver therapy and were changed to oral folic acid are today—over a year later—in the same, or better, condition than when the change was made.

It is a fact that the response of sprue to folic acid may be facilitated by an accompanying adequate diet, but the same thing holds true of liver extract.

We have yet to see, in this part of the world, any harmful effect that could be attributed to the administration of pteroylglutamic acid

## BOOK REVIEWS

*Neuropathology in its Clinicopathologic Aspects.* By I Mark Scheinker, M D. With a foreword by Tracy J Putnam M D 8<sup>th</sup> cloth, 306 pp, with 208 illustrations. Springfield, Illinois Charles C Thomas, 1947 \$6.75

This short book on neuropathology emphasizes the more frequent diseases of the nervous system — those likely to be encountered in the practice of medicine. The material is designed for the practitioner, many of the finer details of neuropathology and descriptions of the rarer conditions have been either abbreviated or left out altogether. The diseases considered are presented in an excellent, clear style, the case histories are brief and add to the value of the book in view of its primary aim. The illustrations are well produced although many of them lack the fine details of delineation associated with most books on the subject. The bibliography and index are adequate. In spite of the fact that there are many books available on the subject, this volume should be considered useful in its limited field.

*A Prelude to Modern Science. Being a discussion of the history sources and circumstances of the "Tabulae Anatomicae Sex of Vesalius"* by Charles Singer and C Rabin. Publications of the Wellcome Historical Medical Museum New Series, No 1 F<sup>o</sup> cloth 58 pp with 59 illustrations Cambridge University Press, 1946.

This folio volume dedicated to D Arcy Thompson and Charles Sherrington, is a discussion of the history sources and circumstances of the six anatomic tables of Vesalius first published in 1538, the precursors of his *De Fabrica Corporis Humani* of 1543 and a prelude to all modern science. The authors seek by their study to display some of the forces that converge to make Vesalius a figure of such scientific importance as the father of modern anatomy and some of the currents of sixteenth century thought that enter into his work.

In the *Tabulae* of 1538 renaissance classical scholarship was grafted on medical tradition. Renaissance art was late in influencing anatomy. The *Tabulae* of Vesalius contained the first attempt to represent the vascular system by drawing but graphic anatomy soon destroyed astrologic medicine. The *Tabulae* themselves like incunabula were printed from wood blocks. The first three, drawn by Vesalius himself illustrate the Galenic physiology of the liver and portal system of the liver and venae cavae and of the heart and arterial system. The last three, representing the anterior lateral and posterior aspects of the skeleton with many postural faults were drawn by van Calcar an inferior pupil of Titian.

Born at Brussels in 1514 and educated at Louvain Vesalius went in 1533 to Paris, where Sylvius (Du Bois) had begun teaching in 1531. Estienne though ten years older than Vesalius did not take his medical degree until six years later. Vesalius began to dissect at Paris for Gnanther but returned in 1536 to Louvain where he dissected his first female body and found a corpus luteum and in the same year prepared his first complete skeleton.

In 1537 Vesalius went to Italy where his chief predecessors had been the humanist anatomists Valla of Venice, Benedectus of Padua, Benevienti of Florence and Gerbi and Acheli of Padua and Bologna. The first early Italian illustrated anatomies to appear were those of Berengar of Capri about 1520 and Massa of Venice in 1536.

The authors further describe Galenic physiology and its Latin presentation and discuss certain anatomic elements in the *Tabulae* constituting ideal material for the study of renaissance anatomic vocabulary, which consists of classical and semitic elements in about equal parts. The Hebrew and Arabic influences in anatomic nomenclature are studied in detail particularly the passage of Arabic terminology to the Latin West.

Finally the authors translate into English with learned commentary, the entire Latin text of the *Tabulae*, includ-

ing a discussion of many of the associated Arabic, Greek and Hebrew terms, and at the end of the volume the six *Tabulae* and their accompanying text are reproduced in facsimile reduction to about half diameter. Besides the *Tabulae* this volume is illustrated with fifty nine figures reproduced from various medieval sources and concludes with four indexes respectively in English, Greek Arabic and Hebrew. It is a memorable and monumental work of scholarship and a priceless treasure to all students and teachers of anatomy and of medical history.

*Cineplasty.* By Henry H Keeler, M D, Ph D. With a foreword by Ross T McIntire Vice Admiral (MC), U S N the Surgeon General, United States Navy 8<sup>th</sup>, cloth, 201 pp, with 199 illustrations. Springfield, Illinois Charles C Thomas, 1947 \$6.75

This book is written by the foremost authority and advocate of cineplastic amputations in the United States. He outlines its history and early attempts and then discusses the indications and technique for this procedure in both the upper and the lower portions of the arm. The aftercare and the rehabilitation of the patient are discussed in detail. This is an excellent monograph well written and well illustrated. It should be in the hands of all surgeons who perform amputations.

*Arthritis and Related Conditions.* Edited by Theodore F Bach, M D 8<sup>th</sup>, cloth 472 pp with 139 illustrations Philadelphia F A Davis Company 1947 \$6.50

Bach has attempted to write a concise readable book for the general physician. This book was begun by the late Dr R Garfield Snyder whose contributions have been retained for the most part. The book begins with an excellent résumé of the history of arthritis. Diagnostic aids are then evaluated. Special chapters are contributed by well known men. The book gives a practical concise picture of the various forms of arthritis and their treatment. It is unfortunate that the author uses many old pictures, borrowed from exhibits of the American Rheumatism Association in the early part of the past decade. Many of the other pictures are not clear. More and better pictures would have greatly improved the teaching value of this book. One would prefer to see the usually accepted nomenclature, rather than "atrophic" and "hyper trophic arthritis" used. The book can be recommended as a good review of knowledge, with adequate directions for treatment for the general physician.

*The Engrammes of Psychiatry.* By J C Nielsen M D and George N Thompson, M D 8<sup>th</sup>, cloth, 509 pp with 28 illustrations. Springfield Illinois Charles C Thomas 1947 \$6.75

With this book the authors have provided a new treatise which differs from others because of its basic underlying principles. The volume is a presentation of psychiatric material, seen in the light of neurologic and bioanatomic concepts. It is, as the authors state, "a system of biological psychiatry where the Engrammes — the neuronal patterns of normal and abnormal thoughts and behavior are delineated gathered and systematized." This approach is fully elaborated in the first part, in which the various concepts of consciousness, emotions, perception, recognition and so forth are exposed against a background of neuroanatomic and physiologic knowledge.

The clinical part of the work however is somewhat uneven in some chapters as in the one on schizophrenia, the psychopathology of the disturbance is too briefly surveyed and quite superficially handled. The authors claim not to have had any desire of bringing new theories or new dynamics of interpretation of mental diseases into this book but simply to present all the psychiatric material that can be supported by physiologic explanation. The chapter on psychosomatic medicine seems to be up to date and constitutes a reference that is not found in previous textbooks of this type. The didactic material is interspersed with many clinical cases — most of them personal experiences of the authors — and some of them worth being remembered.

The style is easily phrased and, for this reason under standable by the average student. A good-sized bibliography gives possibility of further reference in many of the topics discussed.

*Deep Analysis The clinical study of an individual case* By Charles Berg, M D (Lond ), D P M 8°, cloth, 254 pp New York W W Norton & Company, Inc, 1947 \$3 50

This book is devoted to the psychoanalytical study of one case. The work is divided into three parts, which are entitled "Part I, Father," "Part II, Mother" and "Part III, Son." In Part I, a glimpse of the technic and method of procedure is given. Transference takes place, and the emergence of a father fixation is also seen in this section. Part II consists of further interviews and the emergence of the mother fixation from beneath the father fixation. In Part III, the subject gains psychologic emancipation, and the author makes a point of stating, "Life has to be lived to be known and the analytical amelioration has to be experienced to be appreciated." How successfully the subject was emancipated after his analysis may be gauged by the author's statement "He [the subject] had inherited life, and life was already in the process of inheriting him."

The patient displayed many interesting symptoms but during free association he made statements that gave the impression that he had read a number of Freud's works. An attempt has been made by documenting these interviews to give the reader insight into the patient's emotional structure and the mechanisms of his psychic patterns. The book, in the reviewer's opinion, is mainly of interest to the psychiatrist engaged in practicing psychoanalytical therapy.

## NOTICES

### HARVARD MEDICAL SOCIETY

A meeting of the Harvard Medical Society will be held on Tuesday, January 13, at the Massachusetts General Hospital. A symposium will be presented by the Department of Psychiatry of Harvard Medical School.

#### PROGRAM

4 45-6 15 p m, in the Bigelow Amphitheater of the White Building

Problems in Psychotherapy Stanley Cobb, M D

Procedures in Psychotherapy Jacob E Finesinger, M D

Some Contributions of Social Sciences Erich Lindemann, M D

6 30 p m Supper, in East Pay Cafeteria, White Building

8 00 p m, in Lower Out-Patient Amphitheater

Studies with Adreno-cortico-trophic Hormone in Psychoneurotic Patients Harley C Shands, M D, Frederick C Bartter, M D, and Gregory Pincus, Sc D

A Study of the Levels of Consciousness in Pentothal Anesthesia Henry W Miles, M D, and John H Tucci, M D

Some Physiologic Mechanisms Underlying the Electrical Activity of the Brain Mary A B Brazier, Ph D, and Jacob E Finesinger, M D

Subsequent meetings will be held on February 10, March 9, April 13 and May 11.

### NEW ENGLAND SOCIETY OF ANESTHESIOLOGISTS

A meeting of the New England Society of Anesthesiologists will be held in the Bigelow Amphitheater of the White Building, Massachusetts General Hospital, on Tuesday, January 13, at 8:00 p m. Dr John Hugh Tucci will speak on the subject "Pentothal Narcosis and Succinate."

Physicians and medical students are invited to attend.

### FIRST INTERNATIONAL POLIOMYELITIS CONFERENCE

The National Foundation for Infantile Paralysis has announced that it will sponsor the first International Poliomyelitis Conference at the Waldorf-Astoria Hotel, New York City, from July 12 to 17. The State Department has been

requested to transmit invitations to more than sixty foreign governments to send official delegates to the conference. These officials will be asked to present summarizations of the problems of poliomyelitis in their countries at a special session. The presiding officer at this session will be Thomas Parran, M D, surgeon general of the United States Public Health Service.

The program will include scientific and technical papers on research and treatment of poliomyelitis to be presented by professional authorities in the field from this country and abroad. In addition, there will be panel discussions on the various subjects.

Headquarters have been established in the Waldorf-Astoria Hotel under the direction of Stanley E Henwood, of Chicago, who has been appointed executive secretary of the conference. Arrangements for the conference will be directed from there by Mr Henwood. In addition to the sessions, there will be scientific exhibits, demonstrations of muscle testing and treatment procedures, and a film program.

### MISSISSIPPI VALLEY MEDICAL SOCIETY 1948 ESSAY CONTEST

The Eighth Annual Essay Contest of the Mississippi Valley Medical Society will be held in 1948. The society will offer a cash prize of \$100, a gold medal and a certificate of award for the best unpublished essay on any subject of general medical interest (including medical economics and education) and practical value to the general practitioner of medicine. Certificates of merit may also be granted to the physicians whose essays are rated second and third best. Contestants must be members of the American Medical Association who are residents of the United States. The winner will be invited to present his contribution before the thirteenth annual meeting of the Mississippi Valley Medical Society to be held in Springfield, Illinois, September 29 and 30 and October 1, 1948, the Society reserving the exclusive right to first publish the essay in its official publication—the *Mississippi Valley Medical Journal* (incorporating the *Radiologic Review*). All contributions shall be typewritten in English in manuscript form, submitted in five copies, not to exceed 5000 words, and must be received not later than May 1, 1948. The winning essay in the 1947 contest appears in the January, 1948, issue of the *Mississippi Valley Medical Journal*. Further details may be obtained from Harold Swanberg, M D, Secretary, Mississippi Valley Medical Society, 209-224 W C U Building, Quincy, Illinois.

### AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY, INC

The next written examination and review of case histories (Part I) for all candidates will be held in various cities of the United States and Canada on Friday, February 6, 1948.

Arrangements will be made, so far as is possible, for candidates to take the Part I examination (written paper and submission of case records) at places convenient for them. Candidates who successfully complete the Part I examination proceed automatically to the Part II examination to be held May 16-22, 1948, in Washington, D C. Notice of the exact time and place of the Part I and II examinations will be sent all candidates well in advance of the examination date.

For further information and application blanks address Paul Titus, M D, Secretary, 1015 Highland Building, Pittsburgh 6, Pennsylvania.

### POSTGRADUATE ASSEMBLY IN ENDOCRINOLOGY

The Association for the Study of Internal Secretions announces a Postgraduate Assembly in Endocrinology to be held in Los Angeles from February 23 to 28. Applications should be sent to Dr E Kost Shelton, chairman, Committee on Postgraduate Instruction, 921 Westwood Boulevard, Los Angeles 24, California.

## JAMES QUINN LABORATORY

471 Commonwealth Avenue  
 Boston 15, Mass Ken 1356

# SHOULD VITAMIN D BE GIVEN ONLY TO INFANTS?

**V**ITAMIN D has been so successful in preventing rickets during infancy that there has been little emphasis on continuing its use after the second year.

But now a careful histologic study has been made which reveals a startlingly high incidence of rickets in children 2 to 14 years old. Follis, Jackson, Eliot, and Park\* report that postmortem examination of 230 children of this age group showed the total prevalence of rickets to be 46.5%.

Rachitic changes were present as late as the fourteenth year, and the incidence was higher among children dying from acute disease than in those dying of chronic disease.

The authors conclude, "We doubt if slight degrees of rickets, such as we found in many of our children, interfere with health and development, but our studies as a whole afford reason to prolong administration of vitamin D to the age limit of our study, the fourteenth year, and especially indicate the necessity to suspect and to take the necessary measures to guard against rickets in sick children."

\*R H Follis, D. Jackson, M. M. Eliot, and E A Park Prevalence of rickets in children between two and fourteen years of age, Am J Dis. Child 66 1-11, July 1943.

MEAD'S Oleum Percomorphum With Other Fish-Liver Oils and Viosterol is a potent source of vitamins A and D, which is well taken by older children because it can be given in small dosage or capsule form. This ease of administration favors continued year-round use, including periods of illness.

MEAD'S Oleum Percomorphum furnishes 60,000 vitamin A units and 8,500 vitamin D units per gram. Supplied in 10- and 50-cc bottles and bottles of 50 and 250 capsules. Ethically marketed.

## CERTAIN PUBLIC-HEALTH ASPECTS OF INFECTIOUS DISEASES

THOMAS M. RIVERS, M.D., Sc.D.\*

NEW YORK CITY

THERE are at least two ways of viewing infectious diseases, the first is from the standpoint of the individual, and the second is from the standpoint of the community. Curative and preventive medicine usually deals with diseases in individual patients, whereas the handling of them in a community and in relation to environmental factors comes within the realm of public health. In general, each infectious disease shows a characteristic pathogenesis in individual patients, and it is the duty of physicians to have knowledge of this and of how to handle the situation for the benefit of the patients. It is equally true that each infectious disease presents a characteristic pathogenesis in a crowd or in a community, and it is the duty of health officers to know about it and about ways and means of meeting the situation for the benefit of the community. Frequently, it is difficult to determine the point at which the practice of medicine stops and the duties of the health officer begin, many arguments are now in progress concerning this matter. I have no desire to take part in them, for most of them are footless. In passing, however, I should like to register my agreement with Dean Clark's statement "It is safe to say that at least three-fourths of the preventive work made possible by present-day medical science must be carried by the practising physician." The following remarks are limited to certain public-health aspects of infectious diseases, and emphasis is placed on ecologic phenomena.

Dr. Hermann M. Biggs, who died in 1923 and who is considered by most workers to have been one of the greatest figures, if not the greatest, in the history of American public health, made the remark that public health is purchasable, this subject is discussed in greater detail below. The features of infectious diseases that interest workers in the public-health field are their origin, entry into and spread within a community and their control at a community level. Ideas and methods of handling infectious diseases at times undergo rapid and drastic changes. In fact, revolutionary ideas may occur within the lifetime of a single person. This happened to Biggs, who while a candidate for the degree of Bachelor of Arts

at Cornell obtained a leave of absence for a few months to study at Bellevue Hospital Medical College. The influence of that experience is reflected in his baccalaureate thesis, "Sanitary Regulations and the Duty of the State in Regard to Public Hygiene." For the most part, statements in his thesis hold today as well as they did in 1882. However, the accuracy of one remark would be questioned at the present time, in fact, Biggs himself later did much work to show that such a statement was inaccurate. The section referred to is as follows:

It is now universally acknowledged by all medical authorities that a number of these diseases such as cholera, typhoid fever and diphtheria may be generated *de novo* in certain localities from the use of impure water and the existence of unsanitary conditions, and thence are scattered by contagion. And it is now believed by some of the best medical writers that many if not all of the remainder of these diseases such as smallpox, scarlet fever and measles were originally among the so-called filth diseases, and originated from essentially the same conditions as the others. If this is true we are forced to the conclusion that all of these zymotic diseases the most terrible known to man, that have wrought so much misery, desolation and death in the world are the direct results of man's own carelessness and negligence, the inevitable penalty of the violation of sanitary laws.<sup>1</sup>

In 1885, after Biggs had obtained his medical degree, he and Breneman made a similar statement during the investigation of an epidemic of typhoid fever in Plymouth, Pennsylvania:

If it be possible for typhoid fever to originate *de novo* in filthy surroundings and in the use of polluted water, no more remote point need be looked for as a starting point of the disease which spread from a single patient in this house to hundreds in the village. Every thing points therefore to the conclusion that the disease which spread from this house also originated there.<sup>2</sup>

Before Biggs died it had generally been accepted that bacteria and other infectious agents do not arise *de novo* or spontaneously and that diseases caused by them result only from the entrance of such agents into a host. At the time of his death, the present activity in the study of virus diseases had begun but was not far advanced. If he had lived longer, it is obvious, in view of his early statements regarding the spontaneous origin of certain maladies, that he would have been greatly interested in the

\*Director, Hospital of the Rockefeller Institute for Medical Research.

present-day discussions of the origin and nature of viruses

Since the discovery of the first filterable virus in 1892, innumerable observations concerning the nature of these active agents have appeared. The outstanding work of Stanley<sup>3</sup> in 1935, which resulted in the crystallization of tobacco mosaic virus, has precipitated another epidemic of discussions, many of which are reminiscent of older arguments concerning the spontaneous origin of mice, worms, flies, bees and bacteria. In fact, a few workers within the last twenty years have contended that they have experimentally produced viruses from normal bacteria or from normal mammalian tissues. None of these experiments have been confirmed or generally accepted. At least most of us account for positive results on the basis of the presence of latent, unrecognized viruses in the so-called "normal tissues" or other biologic materials used in the experiments.

### NATURE OF VIRUSES

The demonstration that certain plant viruses are crystalline nucleoproteins has left a deep impression upon the scientific world in general and upon the chemists in particular who take the attitude that all viruses are crystalline nucleoproteins. Of course this is not true, but it is difficult to get certain people to believe that it is not. Viruses are not all alike, and they vary greatly in complexity. Some of them are very complex—for instance, the elementary bodies of vaccinia, which have been thoroughly studied, approach the size and complexity of small bacteria. The one characteristic common to all viruses is that they are obligate parasites in the sense that no one has ever induced them to multiply outside a living susceptible host cell.

As a result of recent discussions on the origin and nature of viruses, I have heard it asked "What is the use of attempting to prevent the spread of virus diseases if viruses are fabricated by their hosts?" Physicians, public-health officers and others interested in public-health problems should not become alarmed or misled by such questions or statements. In spite of a few unsubstantiated claims to the contrary, no case of a virus disease arising spontaneously in a patient has been established. Indeed, all the evidence points to the fact that virus diseases, regardless of the nature of the active agents inducing them, will act in the future as they have in the past—that is, a patient who comes down with a virus ailment will do so because, in some manner, he contracted the infection from without rather than through its spontaneous fabrication within. In other words, when one is developing plans for the control of virus maladies, there is as yet no reason to alter current ideas regarding the importance of obligate communicability in the origin and spread of virus infections.

In view of what has been said, it remains to explain why certain virus diseases of human beings have appeared on the horizon within the last twenty

to twenty-five years. This applies particularly to recently discovered virus diseases that attack the central nervous system of man. An obvious answer is that at least some of them had been present for a long time and were not recognized because of the lack of adequate technics. In spite of this obvious answer, it is still strange that St. Louis encephalitis suddenly appeared in 1933 and has not been traced back any farther than to a small outbreak, which occurred in Paris, Illinois, in 1932. Although another epidemic appeared in St. Louis in 1937 and the disease is known to occur sporadically in certain Western States, it has never caused any trouble on the Eastern seaboard. This disease leaves neutralizing antibodies in the blood of patients who recover. Therefore, it is possible to say that human beings in certain parts of the world have not as yet been infected by this virus. Where the virus was before it attacked human beings in 1932 and 1933 is not known. This is a peculiar situation, and there is no adequate explanation for what has occurred. However, one is permitted to speculate concerning the matter, and there are data that enable one to speculate with some hope of arriving at a true answer.

It is characteristic of many viruses to undergo certain changes similar in some respects to those resulting from mutation. Also, a number of viruses possess the ability of adapting themselves to different hosts. Within recent years, seven or eight new viruses have been recovered from wild mosquitoes caught in nature. Most of these viruses are able to attack the central nervous system of experimental animals and to produce encephalitis. There is also evidence that some of the viruses have infected human beings without producing recognizable disease. The evidence for this is the presence of neutralizing antibodies in the blood of certain people living in the areas where the viruses were discovered in mosquitoes. It is conceivable that through mutation, adaptation or change in environment certain viruses, which parasitize only mosquitoes and lower animals, suddenly acquire the ability of producing encephalitis in human beings. Certainly this explanation for the appearance of St. Louis encephalitis is more plausible than one based on the spontaneous fabrication of encephalitic viruses in human beings. Such a statement must not be interpreted as a denial of the spontaneous origin of infectious diseases in the past or of its possibility in the future. However, one can safely say that nobody has yet established the spontaneous origin of a single infectious disease and that regarding such diseases the law of obligate communicability still prevails.

### INFECTIOUS DISEASES IN THE COMMUNITY

#### *Etiology*

Infectious diseases are caused by protozoa, fungi, bacteria, spirochetes, rickettsiae and viruses. These agents are endowed with life. All living things have

an ecology and those producing disease are no exceptions. Some of the viruses may not be alive, and yet their ecology, if the word may be used in this context, is so similar to that of living things that they may, for the purpose of this discussion, be considered collectively with other infectious agents. The behavior of infectious diseases in a population is nothing more than an expression of conflicts between various forms of life in an effort to arrive at a satisfactory equilibrium.

Studies of epidemics have been going on for centuries and have been fruitful. Only recently, however, have such investigations been brought within laboratory walls so that controlled experiments of certain types could be performed. Most of the work has been done by Topley and Greenwood in England and Webster and his associates in America. It has been conducted on mice as the experimental host and *Salmonella enteritidis* (*Bacillus enteritidis*), *S. aertrycke* (*B. aertrycke*) and the virus of ectromelia as the infectious agents.

A brief account of how those experiments were performed and a statement of the results will simplify the rest of this discussion. If 100 mice, all of which are free from *S. enteritidis*, are placed in a cage of such size that they are considered to be living under crowded conditions, the animals will get along fairly well. However, if several mice infected with *S. enteritidis* are placed in the cage, infection will spread to the healthy mice, and an epidemic will occur. Many of the animals will die and the epidemic will finally come to an end, but the infection will not disappear entirely from the remaining population; it will smoulder along, and an occasional mouse will die. At this stage, the disease is usually spoken of as being endemic. If at this point in an experiment several healthy mice are added to the cage daily, after a number of days a new epidemic will occur involving the healthy mice in addition to some of those that have passed through the preceding epidemic. If the addition of mice is stopped, the epidemic will subside again, but if the daily addition of a sufficient number of mice is continued, the epidemic will also continue more or less indefinitely. Once such a population of mice becomes seeded with infection, it is very difficult to eradicate it. Topley and his co-workers have attempted to inhibit the occurrence of epidemics by vaccination of mice before addition to the colony. According to them it is impossible in this manner to prevent epidemics completely.

It might be profitable to examine briefly the biological aspects of the observations described above. *S. enteritidis* is a parasitic organism that has difficulty in maintaining itself free in nature; it is more or less dependent upon some host for its continued existence. The experimental epidemics described resulted from a conflict between infectious organisms and hosts. Had *S. enteritidis* killed all the mice, its continued existence would not have been possible. Eventually, a stabilization of infection was effected,

at either the endemic or the epidemic level, depending upon the conditions under which the experiments were conducted. Only in this way could the infecting agent and the host have continued to live together.

Frequently, military-training camps have unwittingly been set up and run in a manner that duplicated the experiments in mice described above. Many healthy men were brought together from different parts of the country, and after a time these populations became seeded with pathogenic organisms, whereupon occasional cases of infection began to appear. Then, several times a week for long periods, groups of new, susceptible men were added to the populations in the camps. As should have been expected, epidemics occurred, and in some camps the incidence of certain diseases remained at epidemic levels for many months. This was particularly true of some respiratory diseases, as best exemplified by hemolytic streptococcus infections.

The experiments in mice, which present a relatively simple picture of how infectious agents act in a crowd, represent in a general way what takes place in most epidemic diseases of human populations. In each instance, hosts and infecting agents strive to keep for themselves a place in the world. The conflicts seesaw back and forth over long periods with epidemics separated by more or less quiet endemic periods. In many instances, neither the host nor the invading agent attains complete supremacy, and eventually some kind of truce is called or an equilibrium is reached. An ideal situation would be one in which both the infectious agent and host could survive without much harm to either. Theobald Smith<sup>4</sup> often referred to ideal parasites, which, according to him, are infectious agents that live peaceably with their hosts. In other words, they infect and immunize their hosts without causing much damage while preserving for themselves a safe place in nature.

In certain instances, equilibriums between human populations and infecting agents have been attained but, for many reasons, have been maintained with difficulty. The rapid addition of susceptible persons through birth or immigration to a population in equilibrium with a pathogenic agent sooner or later results in an epidemic. This is best exemplified by measles, which occurs every two or three years in large cities. There are many other ways in which equilibriums can be upset. Many of these are present during periods of war, when large groups of human beings are dislocated and sanitary conditions and standards of living are poor. The changes that occur under such conditions are more comprehensible than the other variations that have been noted in the behavior of certain epidemic diseases. For example, scarlet fever at present is extremely mild in certain parts of the world, but forty or fifty years ago it was a scourge; there had previously been another period when the disease was relatively mild. Such cycles

in several other diseases have been noted, but no one has adequately explained the phenomenon

### *Transmission*

In general, there are three ways in which infectious agents get from a sick person or carrier to a healthy, susceptible person by droplet infection, droplet nuclei or contact in respiratory diseases such as measles, influenza and scarlet fever, by means of contaminated water, milk or food or by contact in enteric diseases such as typhoid fever, bacillary dysentery and amebic dysentery, and by means of vectors — for example, mosquitoes in malaria and lice in epidemic typhus. Chapin<sup>5</sup> stressed contact infection, more recently, this mode of spread of infection has not been considered very seriously in many diseases, particularly those in which the infectious agent is found in the feces, such as poliomyelitis, infectious hepatitis and dysentery. My experience with hookworm on Guam impressed me with the fact that most of us and our clothes are at times dangerously contaminated with fecal material. For example, a young infant infected with hookworm was placed on a small cotton blanket for twenty-four hours. At the end of that time examination revealed no obvious fecal contamination, and yet when the blanket was moistened and allowed to stand for five days, 20,000 infective hookworm larvae were obtained.

So far, I have discussed situations in which the relation between the infecting agent and the host has been a direct one and in which the maintenance of disease has involved the ecology of only the infecting agent and the host. The diseases spread by the first two methods mentioned are of this kind. Those spread by vectors are ecologically more complex, because, in addition to the ecology of the host and parasite, that of a vector and at times an intermediate host must be considered. A knowledge of these additional factors is essential for the understanding and control of such epidemic diseases as malaria and murine typhus. Thus, for malaria to flourish in a locality, a sufficient density of *Anopheles* mosquitoes capable of transmitting plasmodia is essential. This means that the mosquitoes must be able to find suitable living and breeding places and to protect themselves against natural enemies. This is an ecologic problem so far as a mosquito is concerned. Likewise, if murine typhus is to be established and maintained in a community, there must be a sufficient number of rats to act as reservoirs for the rickettsiae and the proper kind of fleas to transmit them from rats to human beings. Thus, the maintenance of murine typhus in a community and its behavior in regard to endemicity and epidemicity depend upon the ecology of human beings, rickettsiae, rats and fleas.

### *Prevention and Control*

The most common methods of prevention and control of infectious diseases in human populations are

as follows: quarantine, protection of food, milk and water and other aspects of general sanitation, the eradication or control of vectors, reservoirs and intermediate hosts, and vaccination. In dealing with certain animal and plant diseases more drastic measures have at times been employed — for example, the ruthless destruction of all susceptible hosts within a prescribed area.

So far as many diseases are concerned, the world has just passed through a very interesting period. Certain of them unexpectedly gave trouble, whereas others that had been greatly feared remained in the background. Many procedures for the control of a variety of diseases were instituted, some of which have been publicized as having been very successful, in others much faith was reposed in spite of the fact that there was inadequate evidence to justify such an attitude.

In World War I, epidemics of measles complicated by pneumonia presented serious problems for the United States Army. Most men reared in urban communities had had the disease by the time they joined the military forces, whereas many of those from rural districts had never experienced measles. The epidemics occurred in the susceptible soldiers from rural communities. Between World War I and World War II, good roads and numerous automobiles made much of the United States, so far as measles is concerned, urban in character. Consequently, most of the men who joined the Army or the Navy during the last conflict had had measles prior to their enlistment, and this disease, as predicted by some, was of minor importance.

In World War I, influenza was a major scourge and swept the whole world, killing many millions of people. When World War II broke out, investigators predicted that another pandemic of influenza would sweep everything before it. This did not occur, and influenza proved to be of relatively minor importance. Between the two wars, it was shown that influenza can be caused by at least two agents: influenza A virus and influenza B virus. Furthermore, a vaccine capable of protecting approximately 75 per cent of those receiving it has been perfected and was given to certain military personnel. Even the most ardent advocates of influenza vaccines admit that the prevention of a pandemic during World War II did not depend upon their use. In fact, most workers are reluctant to venture an explanation of what happened. Perhaps I shall be forgiven for suggesting one. Between the two World Wars, rapid transportation of all kinds developed by leaps and bounds, making the world one community so far as influenza is concerned. It has been demonstrated that the two known influenza viruses from time to time produce mild or moderate epidemics here and there throughout the world. In view of this, all populations of the world are probably thoroughly seeded with the two viruses, and something similar to a truce has been declared between them and

human beings. If this is true, we shall continue to have mild and moderate epidemics of influenza but never another pandemic similar to the one experienced in 1918, unless a variant, to which a large proportion of the people in the world are susceptible, suddenly originates from one of the two known influenza viruses.

Unlike measles and influenza, which belong to the respiratory group of diseases and are spread by droplet infection, droplet nuclei and contact, typhoid and paratyphoid fever are members of the enteric group and are usually transmitted by means of infected water, food or milk and by contact. These diseases have played a prominent part in most wars. In the United States Army, however, they were of minor importance in both wars. Compulsory vaccination against typhoid and paratyphoid fever was enforced in the American Army during these wars, and many observers attribute their absence to this procedure. There are still a few workers who believe that typhoid vaccination is of no value. The truth probably lies between these two opinions. It must be remembered that enteric diseases in many countries were well on the way to being controlled long before the use of vaccines. In fact, considerable progress had been made in the control of typhoid fever in England before the discovery of the typhoid bacillus. The control measures consisted of protecting food, milk and water from contamination by enteric bacteria. At the time vaccination was introduced in the American military forces, better sanitation was also provided for the men, even under fighting conditions. In spite of a few contrary opinions, it is hard for me, because of my experience in the Pacific area, to believe that typhoid vaccination as practiced in the American military forces is without value. Nevertheless, from certain things that happened in the Pacific area and in Europe, it is obvious that vaccination in the absence of proper sanitation will not give complete protection against the disease. Members of United States Naval Medical Research Unit No. 2 had an opportunity to study typhoid and paratyphoid fever in troops that took part in the fighting on Okinawa. In all cases studied the men had been adequately vaccinated or re-vaccinated within a year of the time that they became ill. There can be no doubt of the diagnoses. Some of the infections were severe, but most of them either were mild or had been altered in some way. On questioning, practically all the infected men gave a history of having eaten raw vegetables gathered during combat from native fields that had been heavily fertilized with human feces. These men had obviously become infected even though they had been vaccinated. On the other hand, inspection of the natives and their habits forces the conclusion that many more soldiers would have contracted typhoid or paratyphoid fever had they not been vaccinated. I have been told on good authority that American men detained in some of the German

prison camps, where proper sanitation was lacking, suffered from typhoid and paratyphoid fever in spite of having been adequately vaccinated. In a civilian population, enteric infections should be controlled through proper sanitary measures and personal habits. In time of war, particularly in the fighting forces, it may not be possible always to maintain proper sanitation and control of personal habits. Under such conditions, vaccination should be employed, but it must be remembered that even in the armed forces sanitation cannot be disregarded if enteric diseases are to be kept in a position of minor importance.

Each year, malaria is responsible for more sickness and deaths throughout the world than any other disease. The American forces expected malaria in the South Pacific area, but the early handling of the malarial problem in that area was not brilliant. Defects, however, were rapidly rectified, and the problem in the latter part of the Pacific struggle was handled better. When the war ended quinine (Atabrine) was still being used for the suppression of the disease. This drug does not prevent infection. Great efforts were made in America and in England to find true prophylactic and curative agents, both countries believe that they have made progress toward this goal. It will be interesting to observe what the new drugs will do toward controlling or eradicating malaria.

Before World War II, great strides had been made in the control of mosquitoes by means of oil, Paris green and freon-pyrethrum mixtures. During the war, DDT was added to the list of insecticides of value for use against Anopheline larvae and adults. The occurrence and persistence of malaria among human beings depend upon the ecology of Anopheline mosquitoes, of which there are many kinds, each one has an ecology of its own. Methods of controlling or eradicating one kind do not necessarily apply to another. Anopheline mosquitoes are not found on certain islands in the Pacific area, and great efforts have recently been made in many directions to prevent their introduction. Much has been said about the success of these efforts. Having spent some time in the South Pacific and Central Pacific areas and having seen how control measures were carried out, I wonder whether they had much to do with the successes mentioned. In any event, these areas remained free for centuries before institution of the control measures. Therefore, I suspect that there is some ecologic reason why Anopheline mosquitoes find it impossible or difficult to establish themselves in one of the areas. Attempts should be made to establish Anopheline mosquitoes on a small, unimportant island. If the results of the experiment were negative, desirable information would have been obtained, if they were positive, it should not be difficult to eradicate the mosquitoes.

I have discussed this matter with a number of people, who usually show little enthusiasm for the

idea that it would be difficult to establish Anopheline mosquitoes on Pacific islands now free from them. They point to the fact that *Anopheles gambiae* was taken from Africa and established in Brazil, an entirely new habitat. They also point out that this mosquito recently spread up the Nile into a territory where it had not previously been found. It is admitted that some Anopheline mosquitoes can establish themselves in new homes, but it must be remembered that others had already found suitable habitats in Brazil and Egypt before *Anopheles gambiae* joined them. Consequently, I do not believe that anyone should state that Anopheline mosquitoes can establish themselves on certain islands in the Pacific area merely because *Anopheles gambiae* was able to find new homes for itself in Brazil and Egypt.

In speaking of recent advances in the fight against malaria, one writer has made the following statement: "But the most important lesson is that malaria can be controlled anywhere in the world, in any environment, when trained and organized personnel are given the necessary supplies and authority."<sup>6</sup> It is true that much can be done in the control of many Anopheline mosquitoes, but the eradication of a species is very difficult. It is an established fact that *Anopheles gambiae* was eradicated from Brazil and Egypt, but it is also a fact that other Anopheline mosquitoes in Brazil and Egypt were not eradicated at the same time. It has been suggested that a recently implanted species might be more easily eradicated than one that had been established for centuries in an area. Thus, one might doubt whether it would be possible or practicable at present to eradicate *Anopheles gambiae* from its well established African home. At least, an effort should be made to ascertain how difficult it is to eradicate Anopheline mosquitoes from a long-established stronghold. The island of Sardinia has been mentioned as a place where such work might be done with profit.

Polio myelitis came into prominence a little more than a century ago, although it had undoubtedly been present in various parts of the world for a long time. The virus has been found in the nasopharyngeal secretions and feces of patients and contacts. It has also been demonstrated in sewage of communities in which the disease was active and in flies collected in such communities. Since the virus is in feces and since it is admitted that a virus entering the mouth can infect a human being, it is obvious that contaminated water, milk and food can at times lead to outbreaks of the disease. In fact, several epidemics caused by contaminated milk have been reported. In spite of this, most workers in the field believe that the mechanism described above is not necessary for the usual spread of the virus in a population.

As a rule, epidemics of polio myelitis are not explosive. The disease appears to spread radially from

a given point or area, the cases becoming fewer as the distance from the center of the area increases. Furthermore, once someone in a family becomes infected, the family frequently acts as an epidemiologic unit. This type of transmission is not characteristic of diseases usually disseminated through water and milk and is more like those that are spread by droplet infection, droplet nuclei and contact. Since more viruses are found and persist in feces for much longer periods than in the nasopharyngeal secretions, most workers in this field are inclined to believe that through contact of various kinds the virus in the feces of an infected person is transported to the mouths of susceptible people.

As stated above, polio myelitis became epidemic a little more than a century ago and was noted at that time in certain parts of Europe. It did not become very obvious in the United States until the latter part of the last century, since when it seems to have been increasing in prevalence. It is believed that this is a real increase in the number of obvious cases and is not to be explained by more frequent diagnosis. During this period in the United States many infectious diseases, particularly those due to poor sanitary conditions, have decreased in prevalence. This seems to be a paradox: the cleaner the country becomes, the more cases of polio myelitis occur.

It is known that the virus of polio myelitis can induce inapparent infections and a mild disease without paralysis as well as a paralytic disease. In fact, there are only a few paralytic cases in comparison to the other kinds. There are neutralizing antibodies against the virus in 85 to 90 per cent of the adult population tested in the United States. In Africa (particularly in Egypt), China and Japan, it has been shown that at least 85 to 90 per cent of the adult population possess neutralizing antibodies against the virus. In spite of the fact that most adults of these countries possess neutralizing antibodies, very few cases of paralytic polio myelitis are seen. As is well known, the sanitary conditions are very poor, and the countries are densely populated—a condition enhancing the likelihood of the spread of a disease by contact.

Paralytic polio myelitis is very rare in young infants, particularly in those under six months of age. It is also known that antibodies against this disease are transmitted from an immune mother to her infant. These antibodies, like those against other infectious diseases, disappear within six to twelve months after birth. If the virus in Egypt, China and Japan is widely distributed and most infants born in those countries are likely to come in contact with the virus one or more times during the early months of life when they are partially protected by antibodies obtained from their mothers, the infants could, through mild unrecognized infections, develop an active immunity that would protect them from a paralytic attack of the disease in childhood.

or adult life. Thus, if the circumstances described are true, the populations of Egypt, China and Japan have arrived at a truce with the virus of poliomyelitis. In other words, the people and virus live happily together. If the equilibrium that now exists were upset by a marked decrease in the density of the population or by the institution of sanitary conditions equal to those in the United States, it is conceivable that a sufficient number of infants would not become actively immunized early in life and that epidemics of paralytic poliomyelitis would make their appearance.

Public-health officials will probably take exception to some of the ideas set forth concerning poliomyelitis. Nevertheless, the likes and dislikes of public-health officials cannot change ecologic laws, and in the control of diseases many things must be kept in mind. If a population is in happy equilibrium with an infectious agent, it may not always be advisable to disturb this equilibrium unless the disease can be eradicated, unless adequate methods for prevention of its re-entry into the population are available or unless an adequate method is at hand for its control upon re-entry.

At present there is no means of controlling the spread of poliomyelitis, and there is no vaccine available for its prevention. If the disease is transmitted by contact or if it is air borne, public-health officials cannot, through the passage of sanitary regulations, break the chain of events sufficiently to stop the spread of the disease, because legislation against human contacts and against breathing are not acceptable. It is true that personal habits can be improved through education, and many experiments are under way in which, through ultraviolet irradiation or aerosols, attempts are being made to sterilize the air. The experiments are interesting, but it is not likely that sterile air will be universally available for a long time.

Quarantine, which is the detention in isolation of contacts and patients with diseases, has been one of the measures employed in the past to prevent dissemination of infectious maladies within a country or from one country to another. Much faith has been placed in this method, but most experienced health officers and epidemiologists are well aware of the fact that quarantine as applied to human diseases, because human nature will never permit it to be sufficiently stringent, offers no great barrier to their spread. In many places, for psychologic reasons if not from ignorance, outmoded quarantine is still in effect, resulting in the waste of much time and money. So far as I know, no epidemic of measles, chicken pox, influenza, poliomyelitis, smallpox and so forth has ever been adequately controlled by means of quarantine. The Board of Health of the City of New York is gradually making isolation or quarantine regulations less and less burdensome to its citizens. At present the regulations are very

mild and simple, and it looks as though many of them will soon be dispensed with entirely.

Since 1815 a number of pandemics of cholera have occurred. Indeed, the disease has been known to spread to many parts of the United States. At times quarantine measures were very strict. Did they do any good? I doubt it. In any event, Greenwood<sup>7</sup> has made the following observations concerning the value of quarantine measures in controlling this disease:

As seems so often to be my fate I must end on a note of interrogation. Why did the Indian variety of cholera acquire a dispersive power a little more than a century ago? Why did it ravage Europe for more than a generation and then lose interest in us? Without going the whole way with Stucker I am prepared to go some distance and to doubt whether the decisions of national and international committees or the blockading of land or sea frontiers have played a much more important rôle than the fly on the wheel.

There is a definite relation between the prevalence and persistence of certain diseases and the sanitary conditions and standards of living. The best way for a country to prevent the entrance and spread of such diseases is to have a civilization and a standard of living that provide poor ecologic conditions for the infectious agents, their vectors and reservoirs. For example, it is not necessary at present to worry about the introduction of cholera and epidemic typhus into the United States, because they would find unfavorable conditions for their establishment and spread.

The statement of Biggs, mentioned above, that public health is purchasable is true within certain limits, one of which is that it cannot be brought alone, there are tie-in purchases, such as the proper kind of civilization and standard of living. Moreover, I strongly suspect that more than one such tie-in purchase has been largely, if not entirely, responsible for specific gains in public-health progress.

Early in the history of this country, malaria was rampant in the Mohawk Valley. It is doubtful whether conscious efforts to do away with Anopheles mosquitoes in that area accomplished much, but, as the fertile land was brought under cultivation, the area became more and more densely populated, with the consequent removal of breeding places for the mosquitoes. Thus, with the advance of civilization, malaria-bearing mosquitoes found ecologic conditions unfavorable for them, and malaria disappeared from the area without any conscious efforts on the part of the inhabitants.

The death rate from tuberculosis in the United States has been decreasing rapidly. Public-health officials and public-spirited organizations have been active, and there is a tendency on their part to ascribe the decrease to their activities. Similar claims have been made regarding many other infectious diseases, as exemplified by the following statement by Grant<sup>8</sup>:

The achievement of health departments in controlling sanitation of the environment and the incidence of communicable diseases with the consequent improvement in mortality rates has already resulted in the well known marked shifts in the age distribution of population and has disclosed the three major lags in medical care, namely, rehabilitation, chronic illness, and mental care.

While health officers and different organizations have been active, many things not directed by them have been happening in the population, and these happenings probably would have occurred in spite of anything that could have been done. I have no quarrel with health officers or with people working in the tuberculosis field, for they have done a good job, but I seriously doubt whether the decrease in incidence of certain infectious diseases and the marked decrease in the death rate from tuberculosis in particular are largely due to their activities instead of resulting from multiple events in the popu-

lation about which too little is known and over which no one has a great deal of control. Undoubtedly, many of these happenings are in some way related to or controlled by ecologic laws

## "FEVER OF UNKNOWN ORIGIN" DUE TO LYMPHOGRANULOMA VENEREUM\*

### Report of a Case with Diagnosis by the Use of Quantitative Complement-Fixation Tests

CAPTAIN NORTON M. LUGER, M.C., A.U.S.†

**L**YMPHOGRANULOMA venereum infection is a localized suppurative process involving the inguinal, femoral and pelvic lymph nodes and the rectum. Although systemic symptoms are common in this disease, prolonged fever is rare. This infection is therefore not usually thought of in the differential diagnoses of febrile conditions. Fever, sweats, headache, tachycardia or relative bradycardia, joint and muscle pains, malaise and anorexia are frequent but, as a rule, cause little concern to the patient. Some cases, however, are so severe that the lymphadenitis appears to be of minor importance in the face of a generalized infection. When generalized symptoms predominate and the tell-tale lymphadenitis is not present, the diagnostic problem presented is no less formidable than the solution of a "fever of unknown origin." In this task, the standard laboratory procedures are of little help.

Recently, such a problem was encountered at the Station Hospital, Camp Lee, Virginia, and its final solution was achieved only through the use of a simple laboratory test that has heretofore had little clinical use—the quantitative complement-fixation test.

#### CASE REPORT

A 33-year-old Negro soldier was first seen at a dispensary on the morning of June 26, 1946, complaining of chills and fever, which had started the night before after an episode of vomiting. He was referred to the hospital and while on the way there he experienced another shaking chill.

\*From the Laboratory and Medical Services, Station Hospital, Camp Lee, Virginia.

†Chief Laboratory Service, Station Hospital, Camp Lee, Virginia.

Physical examination was negative except for a temperature of 103.4°F, a pulse of 104, and respirations of 24. A smear for malarial parasites was also negative. On the day of admission the temperature dropped to 99.4°F and remained normal until June 30, when the patient suffered another chill. On the following morning the temperature was 100.2°F, returning to normal during the same day. He remained afebrile and asymptomatic and was discharged on July 8, no diagnosis having been reached.

On September 9 the patient was readmitted with headaches, chills and fever of 1 week's duration. The chills were true rigors, preceded by nausea and vomiting and followed by long welts on the back and buttocks. A carefully taken history revealed that, in addition to the episode in June, two similar attacks had occurred in early January and mid-March. On both occasions the patient had been treated by a physician with pills for 4 or 5 days, after which the fever subsided.

The past history revealed that in 1945 a diagnosis of latent syphilis, which had been treated with the Army 26-week course of Mapharsen and bismuth† and also 4,000,000 units of penicillin, had been made. He had served in southern France, but not in any tropical theater, and to the best of his knowledge had contracted neither malaria nor any other tropical disease. The review of systems was negative, and he had never noted inguinal adenitis. The family history disclosed that his mother had died of heart disease at the age of 59, a sister had died of unknown cause at the age of 35, and a brother of tuberculosis at 30.

Physical examination disclosed a healthy-appearing, afebrile, young Negro, who was perspiring more than normal. The pupils were equal and reacted to light and accommodation, the extraocular muscles were normal, and there were no abnormalities of the ears, nose or throat. No cervical adenopathy or thyroid enlargement was noted, and the neck was supple. The cardiorespiratory system was normal except for wheezes throughout the whole left lung field, these were absent on later examination. No murmurs, cardiac enlargement or arrhythmia was found. There was slight protuberance of the abdomen, but the liver and spleen were not

†This treatment is as follows: 0.06 gm of Mapharsen intravenously, twice a week for ten weeks, followed by a rest for six weeks, and then another 0.06 gm twice weekly for ten weeks. Bismuth subarsenate, 200 mg intramuscularly is given weekly for five weeks, followed by rest for five weeks, and then six weeks of bismuth, rest for five weeks and, finally five weeks of bismuth.

enlarged and the kidneys were not palpable. According to one observer there was slight bilateral inguinal lymphadenopathy, but this was not confirmed by a second examiner. Genital, rectal and neuromuscular examinations were negative. The diagnosis was "fever of unknown origin."

A ray examination of the chest and analyses of the urine were negative. Examination of the blood revealed a hemoglobin of 12.5 gm. and a white-cell count of 7200. Agglutination tests for *Eberthella typhosa* "O" and H, and *Salmonella schottmulleri* were positive in a titer of 1:80 but negative for *S. paratyphi*, *Pasteurella tularensis*, *Brucella abortus* and *Proteus vulgaris* (Ox19). Two smears for malaria and three blood cultures were negative. The total protein was 6.16 gm per 100 cc., with 4.35 gm of albumin and 1.81 gm of globulin (albumin-globulin ratio of 2.4). Repeated white-cell counts on September 23 and 25 were 5400 and 7600 respectively. Repeated urine analyses were negative. The quantitative Kahn test was reported as 4 Kahn units and the Wassermann test as ++.

For the first 4 hospital days the patient appeared well and was helping the ward attendants. On the 5th day the tem-

other samples of blood. On January 15 and February 3, 1947, the complement fixation titers were 1:40.

### DIAGNOSIS

Four episodes of illness occurred in nine months characterized by chills, fever, diaphoresis and an eruption described by the patient as consisting of welts, each episode being ushered in by headache, anorexia and vomiting. These symptoms and the fever curve were characteristic of a "septic" type of infection. Against a bacterial etiology were the normal white-cell count, several negative blood cultures and negative agglutination tests. (The titers for typhoid and paratyphoid B were those associated with vaccination with "triple typhoid

FIGURE 1 Fever Chart

perature at 8 a.m. was 101 F. and the fever curve assumed an intermittent pattern. There were no rigors, but the patient complained of mild headaches.

In the absence of any diagnosis the patient was seen by officers in the Venereal Disease Section whose opinion was that this syndrome was not due to syphilis, since there were no clinical findings of note and he had been given two adequate courses of therapy. The suggestion was made that a systemic infection with the virus of lymphogranuloma venereum could give such a syndrome. Accordingly, a Frei test was done on September 19, and this was markedly positive in 24 and 48 hours. Blood was drawn for complement fixation tests, and +++++ fixation was obtained in a dilution of 1:160. Unfortunately, no further dilutions were done at that time and the serum was lost, so that the true titer was not obtained. Sulfadiazine in full doses was started the presumptive diagnosis being lymphogranuloma venereum.

From the 1st day of antidiazine therapy the temperature dropped and never rose during the 2 weeks in which the drug was administered (Fig. 1). The patient was sent on convalescent furlough on October 4 and returned on October 16, when he was well and had no complaints. Further complement fixation tests were done to completion at that time and +++++ reactions were obtained in dilutions up to and including 1:640.

The patient was seen again on November 12. By that time he had gained 15 pounds and expressed the opinion that he had not felt so well the whole year. He had experienced no recurrence of any symptoms and the +++++ titer was 1:320.

Shortly after this last examination the patient was discharged from the Army. He co-operated by sending two

vaccine.") During this diagnostic impasse the possibility of a systemic infection with a specific Frei arose, and the diagnosis was made on the basis of a positive Frei test and a positive complement-fixation test. He was then treated with sulfadiazine, and the response was gratifying. Although the therapeutic response is not a specific reaction, the complement-fixation and Frei tests are.

In any group of adult Negroes, a considerable number will be found to have positive Frei tests, various studies disclosing anywhere from 10 to 40 per cent, or more.<sup>1</sup> Thus, the establishment of a diagnosis on the basis of this test alone is hazardous.

The complement-fixation test done in this laboratory uses "Lygranum CF"<sup>2</sup> from a purified preparation of virus grown on chick-embryo yolk sac.<sup>3</sup> The antigen is a specific antigen and has few side reactions of note.<sup>3</sup> In a survey conducted at this hospital no positive reaction (+++++) has been encountered in a serum dilution higher than 1:20 in persons without either clinical lymphogranuloma

<sup>2</sup>The antigen used in this and related studies was supplied by E. R. Squibb & Sons, through the courtesy of Dr. Charles H. Mason.

or a recent history of the disease. Thus, the initial titer of 1 640 is a highly significant one and cannot be considered a false positive. The high titer is also consistent with the long duration of the illness, and a fall in titer is significant diagnostically, as well as therapeutically, since it occurs frequently after treatment with sulfadiazine. A later sample of convalescent serum was sent to the Virus Laboratory of the Army Medical School, where Dr. Joseph Smadel did complement-fixation tests using a different antigen.\* He reported the results as positive in a lower titer (1 32) but was able to ascribe the difference to the use of different antigens.

A diagnosis based on this test raises the problem of infection with a related virus, such as that of psittacosis, the pneumonitis virus of Eaton, the meningopneumonitis virus of Francis and Magill, trachoma and inclusion blenorrhea virus and the virus of mouse pneumonitis (Nigg). The viruses of Nigg and Francis do not produce known infections in human beings, and in the absence of any eye disease, it is hardly possible to incriminate the viruses causing trachoma or inclusion blenorrhea. The absence of any symptoms or signs referable to the respiratory system and the negative x-ray examination of the chest tend to rule out the psittacosis and pneumonitis (Eaton) viruses. In addition, neither of these infections responds to sulfadiazine in such dramatic fashion, nor do they pursue the relapsing course observed in the case reported above. The combination of clinical course, positive Frei test and a high titer of specific complement-fixing antibodies served to establish the diagnosis in this case.

In the past, the diagnosis of these cases was almost impossible early in the disease and could be made only when, after prolonged pyrexia, sometimes extending for over a month, an inguinal mass appeared and suppurated in characteristic fashion. Kornblith<sup>3</sup> reported 2 cases in which this was the sequence of events. In both, there was a septic type of fever of three weeks' duration, the diagnosis was made in one after bilateral suppurative adenitis had supervened and in the other by biopsy of an inflamed inguinal lymph node. D. Luger<sup>4</sup> describes a case of prolonged fever without any localizing symptoms, which was diagnosed as lymphogranuloma venereum by biopsy of a slightly enlarged non-tender inguinal lymph node. In each of these cases there was a history of copulation with Negroes. It is also noteworthy that in each case in white men the diagnosis was made on an average of one month after the onset of fever. Other cases have been reported by Giacardy<sup>5</sup> and Chevallier and Bernard,<sup>6</sup> and Stannus<sup>7</sup> speaks of a typhoidal state occurring in this illness.

An interesting series of infections was reported by Harrop, Rake and Shaffer,<sup>8</sup> involving 3 laboratory workers. One handled infected mice, and 2 inocu-

lated mice intranasally with lymphogranuloma virus. In each of these cases there was headache accompanying chills, sweats and a spiking temperature curve, 2 patients had cervical adenopathy. One of these was given an average of 5 gm. of sulfadiazine daily for nine days, the temperature became normal in seventy-two hours, and there were subsequently no residua of the infection. Another patient had a similar clinical picture and was treated for three days with sulfathiazole (27 gm.). This episode was curtailed, but three recrudescences occurred. During the last attack the treatment with the sulfonamide was vigorous (100 gm.), and no recurrences were noted. There was a rise in complement-fixing antibodies in each case, and positive Frei reactions were present. This latter test became negative in the 2 patients who were given adequate sulfonamide therapy while complement-fixing antibodies were still present in declining titers.

#### PATHOGENESIS AND CLINICAL COURSE

Lymphogranuloma infection can occur in varying severity. Some infections are so mild as to be sub-clinical and are detectable only by the Frei test and by quantitative complement-fixation or virus-neutralization studies.<sup>1</sup> The most frequent forms clinically are those causing inguinal adenitis and proctitis. In these forms the "systemic" signs vary widely in severity, so that some patients are free of fever, malaise and headache, and others are so profoundly prostrated that bacterial sepsis is imitated. Similarly, the lymph nodes may not appear abnormal on physical examination, or they may form an abscess the size of an orange. Thus, any combination of systemic signs and the various grades of lymphadenitis may be present, even the complete absence of both or either.

Histologically, the lymph nodes in this infection show multiple abscesses of varying sizes, which characteristically have a radiate arrangement of the lining epithelioid cells. As the process extends, large accumulations of pus may occur, and when this material is collected and inactivated with heat, it may be used as Frei antigen. When the material or heated cultivated virus is injected intravenously into normal people no reaction is noted, but in infected persons, a temperature rise is noted in twelve to eighteen hours. This reaction was used diagnostically and therapeutically in the past.<sup>9</sup> The fact that material, which is present in the body, is capable of exciting a febrile response suggests a likely method of pathogenesis of the generalized symptoms.

Rake and Jones<sup>10</sup> isolated a fraction from infected yolk and yolk sac that was lethal for mice and postulated that this substance was responsible for the systemic symptoms of this disease. The substance was found in the same fraction that contained the viral elementary bodies, from which it was not separated. It is possible that the "toxic factor" is

\*A suspension of washed psittacosis elementary bodies.

inherent in the virus particles in the manner of an endotoxin

Although the virus has never been isolated from the blood, there is considerable evidence that it can be spread throughout the body by the circulation. Its occurrence in the spinal fluid in patients with inguinal adenitis, but without meningitis, has been described,<sup>11</sup> and meningitis and meningoencephalitis due to this virus has been mentioned in several reports.<sup>12-14</sup> It has been noted experimentally that meningoencephalitis can be produced in mice after intraperitoneal inoculation of virus if the brain is simultaneously traumatized aseptically.<sup>15</sup> It is difficult to conceive of a method of spread in such cases except by the blood stream.

It appears, then, that in the type of infection described above, the virus remains hidden in the body, probably in the lymph nodes, where it may produce anatomic, but subclinical, changes. Periodic release of virus into the blood stream results in symptoms of a general systemic infection similar to those found in bacterial sepsis.

### TREATMENT

Lymphogranuloma may recur unless treatment with sulfadiazine is vigorous and prolonged. Full therapeutic doses cause abrupt remission of systemic symptoms. In Harrop's<sup>6</sup> report, three relapses occurred in a patient who had received sulfonamide for short periods. During the fourth attack, treatment was given for over twenty days, and no recurrences were noted. At this hospital full doses of sulfadiazine (1 gm. every four hours, day and night) have been used for two weeks unless symptoms persist longer. This was the treatment given in the case reported above, and the patient has had no recurrence to date. It is my belief that shorter and less intense courses will be less efficacious.

### Discussion

This type of infection is not fatal. However, extension to the brain and meninges or to the bones and joints is possible,<sup>16</sup> and in view of the prompt response to sulfadiazine, it is desirable that the diagnosis be made early. The majority of cases betray themselves after a period of months, but

the patients become debilitated, anemic and chronically ill. The essential features of the infection are chills, a temperature with daily spikes of fever, sweats, headaches, a normal or slightly elevated white-cell count and a history of sexual promiscuity. Thus, in all cases of fever of hidden origin, when laboratory aid is sought, this type of infection should be considered. The quantitative complement-fixation test will substantiate or eliminate the diagnosis. The procedure is a simple one and can be done by any laboratory equipped to do Wassermann tests.

### SUMMARY

An unusual syndrome caused by the virus of lymphogranuloma venereum is described.

The diagnosis was made by the use of quantitative complement-fixation tests for the virus.

The pathogenesis of this type of infection is discussed.

## THE DISABLED VETERANS OF WORLD WAR II\*

### Analysis of 600 Cases Examined at Harvard University

AUGUSTUS THORNDIKE, M D †

BOSTON

SINCE the termination of hostilities, many sick and wounded veterans have been returning to universities to complete the requirements of their college and graduate-school academic assignments, under the G I Bill (Public Law 346) and the Rehabilitation Bill (Public Law 16) of the Seventy-Eighth Congress. The disabled veteran has been epitomized in the press, radio and motion pictures, and although much is sponsored for his good and although many benefits have been provided for him by a generous government, it seems appropriate to call attention to what a group of six hundred dis-

abled veterans, whether service-connected or not, and that each of these veterans is entitled to the free filling of medicinal prescriptions at the pharmacist's, as well as to free eyeglasses and to free medical consultation service. Through the professional staff of the Hygiene Department and through its board of consultants in the specialties of medicine, a complete medical service is provided free for the disabled veteran at Harvard University. The professional fees of the consultant board are computed at the Blue Shield fee-schedule rate and billed to the Hygiene Department, the University being reim-

abled veterans in one of our universities represent in the way of disabilities.

Harvard University has negotiated a contract with the Veterans Administration, whereby all students enrolled under Public Law 16 are cared for by the Hygiene Department. The responsibility for the entire health and sickness program provided in this law applicable to Harvard students is delegated to the university health department. It is true that very few doctors appreciate the fact that the students receiving benefits under this law are entitled to free care for medical and surgical con-

ditions, whether service-connected or not, and that each of these veterans is entitled to the free filling of medicinal prescriptions at the pharmacist's, as well as to free eyeglasses and to free medical consultation service. Through the professional staff of the Hygiene Department and through its board of consultants in the specialties of medicine, a complete medical service is provided free for the disabled veteran at Harvard University. #### NONCOMBAT-INCURRED DISABILITIES

In an analysis of six hundred consecutive examinations of disabled veterans, it is apparent that a large group of noncombat-incurred disabilities were received in line of duty. With corrections for multiple diagnoses, the noncombat-incurred disabilities represent 60 per cent of the entire group. Perhaps of even greater significance is the fact that 38 per cent

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1947.

†Associate in surgery, Harvard Medical School, associate surgeon, Children's Hospital, chief surgeon, Department of Hygiene, Harvard University.

of these disabilities were due to medical disease (Table 1). Furthermore, an additional 23 per cent — an even greater number of men than that of those who had combat-incurred bone and joint wounds — were caused by orthopedic conditions. Perhaps as the result of screening by the Board of Admissions, neuropsychiatric disabilities do not loom large in this group.

If one considers the noncombat-incurred disabilities from a practical point of view, it is obvious that many of these men have reached the optimum

quire no further medical treatment, even though they still receive disability compensation. In other words, the Government appears to be maintaining certain disability allowances beyond the point of necessity. For example, one man has a 100 per cent disability rating for chronic infections mononucleosis, the most recent symptoms of which occurred sixteen months prior to the most recent physical examination. In the category of noncombat-incurred disabilities, 114 men with medical diseases are receiving \$4570 per month in compensation, an average of \$39.74 per man, and 50 men with

orthopedic conditions are receiving \$1394 per month, an average of \$27.88 per man — a total of

joint wounds (Table 4). Forty-six of these men are receiving disability compensation totaling \$2952 per month — an average of \$64.17 per man. Most of them had a compound fracture, with or without serious complicating involvement.

nerves or other tissues. Since there are still over 5000 men with battle wounds in Army hospitals today, it is obvious that this group does not represent the most serious types of cases. Active osteomyelitis was a rare finding, only 2 cases being observed among the 84 men with healed compound fractures. Only 1 of these patients required hospitalization owing to a minor recurrent abscess due to a small sequestrum. The men with bone-and-joint injuries and those with peripheral-nerve wounds comprise the majority of patients requiring

of those excused for medical reasons among the disabled veterans exceeded by only 3 per cent the figure for the class as a whole, and likewise, the percentages of those qualifying after instruction were reasonably alike in both groups (Fig 2). In an analysis of the participation of 156 disabled veterans and 1786 normal veterans the incidence of the former who were excused from the compulsory sports program was only 5.4 per cent greater than that of the latter (Fig 3). Even more significant is the difference of 1.7 per cent in contact-sports participation between the disabled and nondisabled veteran. From these data, it can only be concluded that many veterans classified as disabled have insignificant disabilities. With over 2,500,000 veterans of World War I and World War II classified as disabled, it appears that many of these men have relatively minor or insignificant handicaps.

### REHABILITATION

Since corrective exercises are of greater importance than physical therapy in the rehabilitation of men with late convalescent disabilities, the Hygiene Department has developed such a program. Mr. Lloyd C. Harper, who has had considerable ex-

FIGURE 2 Physical Fitness in Freshman Class, Harvard College (September, 1946)

further medical treatment, physical therapy and remedial exercise.

### APPRAISAL OF DISABILITY

Perhaps an adequate method of appraising the degree of disability of these veterans is to compare the results of the compulsory physical-training program required in the freshman class. All freshmen are required to take a physical-fitness test known as the "Harvard Step Test," in which they are scored according to an accepted standard of normals. A score of 85 or above is rated as excellent, one of 65 to 84, as satisfactory, and one below 65, as unsatisfactory. The 71 disabled veterans had a higher percentage of excellent ratings than the freshman class as a whole (Fig 1)—an unanticipated finding. As might have been expected, however, a smaller percentage of disabled veterans completed the test satisfactorily, and a greater percentage failed. In the required swimming test, the incidence

FIGURE 3 Comparison of Sports Participation between Public-Law-16 Students and Freshman-Class Veterans (Summer, Fall and Spring Terms, 1946-1947)

perience with the Army reconditioning program, is responsible for these exercises under medical guidance. The Department of Physical Training has provided the gymnasium and has obtained the necessary apparatus and equipment. Individual treatment is afforded all cases at first. With progress in restoration of function, group exercises, including group sports, are recommended. Rowing, swimming, basketball, volleyball and softball are group activities usually provided. There are 10.5 per cent of the 600 disabled veterans now participating in this program.

Those who are familiar with the program of reconditioning and rehabilitation in the Army and Navy hospitals appreciate the values of adequate convalescent care. In returning to civilian life, the severely disabled veteran turns to his family physician, expecting that his permanent disabilities will be treated and improved. Deaver<sup>1</sup> described methods for the rehabilitation to economic independence of the physically handicapped civilian at the Institute for Crippled and Disabled in New York City. Lippman<sup>2</sup> has reported a program of convalescent reconditioning for civilian hospitals. Most hospitals, however, are unable to find space or to obtain the necessary specialized personnel for such an undertaking. Aitken<sup>3</sup> has described an outstanding medically supervised program of rehabilitation, limited in its clientele, for the civilians of New England. Large communities need facilities for rapidly restoring convalescent disabled civilians to gainful occupations. The patient in late convalescence from a serious disability today is the forgotten patient in civilian practice. The rewards of adequate recovery are immeasurable. To increase the average annual wage of 44,000 handicapped retrainees under the 1944 training program of the Office of Vocational Rehabilitation from \$148 to \$1768 is a noteworthy accomplishment.<sup>4</sup> A similar

program would restore a large part of our society — reported to number over 20,000,000\* — from dependency on state, county or city charity to economic independence and productivity.

#### SUMMARY

A study of 600 disabled veteran students in Harvard University demonstrated that 60 per cent of the disabilities are noncombat-incurred and do not cause interference with the pursuit of academic assignments, that a comparison between the abilities of the disabled veteran freshman and those of the class as a whole to participate in compulsory-exercise programs demonstrates an insignificant percentage variation between the two groups, and that the 10.5 per cent of this group requiring further rehabilitation is taking part in a medically supervised remedial-exercise program.

## TOXIC EFFECTS OF GASES AND VAPORS\*

### Mechanism of Poisoning by Volatile Solvents

MARSHALL CLINTON, JR., M.D.†

BUFFALO, NEW YORK

ACCIDENTAL poisoning as a result of the inhalation of toxic gases or vapors is encountered with discouraging frequency. The number of reports in the current literature suggests that the incidence of such poisoning is on the increase. The basic reason for this rise is the recent, rapid increase in the development and industrial use of volatile organic solvents. Unfortunately, accurate statistics concerning these cases are not available in this country for a variety of reasons. The reporting of occupational disease is encouraged by the Commonwealth of Massachusetts, but is not mandatory, complete statistics are therefore not available from this source. Compensation-board records are not too helpful, since their opinions and findings are frequently not accompanied by sufficient objective evidence to permit an evaluation of the cases in question. Furthermore, there is no way to deter-

mine the incidence of accidental poisonings occurring in the home, which may not be recognized or if recognized but not fatal, are usually not reported. The situation regarding determination of the incidence of such poisoning is roughly similar in other states, some being slightly better and many far worse than Massachusetts.

It is believed that many illnesses resulting from the inhalation of toxic gases or vapors are ascribed to other causes. Failure to recognize the etiologic role played by a toxic agent in a given illness stems from a variety of factors. The syndrome produced may resemble in every particular one of several common organic diseases with which the physician is more familiar. The patient is frequently not aware that the air he is breathing contains a noxious agent, and fails to associate the breathing of some odd-smelling but essentially nonirritating air with the occurrence of illness ten days or two weeks later. Many physicians do not appreciate the importance of the respiratory tract as an avenue for the absorption and elimination of large doses of

many toxic agents, and either do not elicit a history of exposure or do not recognize the significance of such a history. It is perhaps advisable, therefore, to present briefly some of the basic principles involved in the absorption of toxic gases and vapors, before consideration of the type of poisonings that

TABLE 1 *Effect of Solubility on Blood Concentration and Total Body Content \**

SUBSTANCE	COEFFICIENT OF DISTRIBUTION	BLOOD CONCENTRATION AT EQUILIBRIUM mg /liter	TOTAL WEIGHT IN BODY gm
Carbon disulfide	2.5	0.25	0.0175

Ethyl alcohol	1300.0	130.0	9.1000
Methyl alcohol	1700.0	170.0	13.9000

\*Air concentration, 0.1 mg per liter

commonly occur and are believed to be unrecognized in many cases

#### ABSORPTION AND ELIMINATION OF GASES AND VAPORS

As air containing a noxious agent is inhaled, some of this air reaches the alveoli. The air in the alveoli comes into virtually complete equilibrium with the

returning to the lungs gradually contains more of the gas or vapor, in solution, so that smaller amounts can be absorbed into the blood from the alveoli and a state of equilibrium — saturation — is gradually approached. When this occurs the body contains as much of the gas or vapor as it can hold in equilibrium with the concentration existing in the inspired air. Under these conditions, the expired air will contain as much of the substance as the inspired air, and additional absorption will occur only as the material already in the body is metabolized or eliminated via other channels.

The actual amount of a given substance that the body can contain when in equilibrium with a given air concentration is quite variable, depending essentially on the solubility of the substance in blood and tissue. It may be expressed in terms of the coefficient of distribution, which may be defined as the ratio of the weight of gas or vapor in equal volumes of air and fluid that are in gaseous equilibrium. A substance that is relatively insoluble in blood or tissue has a low coefficient of distribution, whereas one highly soluble in blood or tissue has a high coefficient (Table 1). The solubility of the substance in blood or tissue also influences the total amount of the substance entering the body;

FIGURE 1 *Representative Respiratory Pattern of a Subject Exposed to 1000 Parts of Ammonia per 1,000,000 Parts of Air*

*The upper record shows the normal response, and the lower that after exposure to ammonia*

blood almost instantly. This, of course, results in a marked lowering of the concentration of the substance in the alveolar air as the blood concentration rises, and less of the toxic agent is exhaled than was taken in. The blood leaving the lungs contains an appreciable amount of the toxic material, which it in turn gives up to the tissues, until blood and tissues reach equilibrium with one another. As the above process is repeated, the capacity of the blood and the tissues to take up more of the agent at the pressure maintained in the alveoli is gradually exhausted, and consequently the venous blood

an average-sized man in equilibrium with air containing 0.1 mg per liter of carbon disulfide will contain a total dose of slightly less than 20 mg of carbon disulfide, whereas a man in equilibrium with the same air concentration of methyl alcohol will contain nearly 14 gm of this substance, or about seven hundred times as much.

Equilibrium is approached rapidly with the relatively insoluble substance, only a small amount of which is required to saturate the body, but is approached slowly with the highly soluble substance, since a large amount is required. Elimina-

tion of substances from the body via the lungs occurs as the reverse of absorption, once exposure is discontinued. The situation is analogous to the filling and emptying of tanks of various sizes through a pipe, the size of the tank representing the solubility of the material in the body and the diameter of the filler pipe the rate of exchange between alveolar air and blood. If the substances have a low coefficient of distribution, the tank is small, equilibrium is achieved rapidly, and elimination via the lungs takes only a short time. If the substances have a high coefficient of distribution the tank is large, equilibrium requires many hours of exposure, and elimination is correspondingly protracted. Some of these absorbed substances, how-

mode and type of interference with the breathing pattern, a series of experiments was carried out in which human subjects inhaled ammonia or trichlorethylene vapor from a large glass-lined tank through a rubber facepiece. The concentrations in the tank were achieved by complete evaporation of an amount of trichlorethylene or concentrated ammonium hydroxide that produced the desired concentration in the volume of air contained by the tank. The tank was connected to the subject's breathing mask by a system of valves that permitted rapid switching from room air to tank air without interruption of the breathing cycle.

The respiratory pattern was recorded by means of the pneumotachograph developed by Silverman,<sup>1</sup>

FIGURE 2 Representative Respiratory Pattern of a Subject Exposed to 10,000 Parts of Trichlorethylene per 1,000,000 Parts of Air. The upper record shows the normal response and the lower that after exposure to trichlorethylene vapor.

ever, are either eliminated by other channels or metabolized in the body. This is analogous to the situation existing when one fills a tank with an open drain—it takes a long time to fill it, but emptying proceeds rapidly.

Exposure to many toxic gases and vapors is self-limiting because of the unpleasant and irritating effects produced by their inhalation. Serious poisoning due to the prolonged inhalation of such agents occurs infrequently, because the exposed person usually removes himself voluntarily from the unpleasant atmosphere. Many other agents are not unpleasant to breathe in concentrations that are capable of producing serious injury to health, so that a person may undergo a sufficiently prolonged exposure to permit the absorption of amounts of the gas or vapor that will produce injury to the body. One of the factors that appears to determine whether a given exposure will be tolerated or will be voluntarily discontinued is the production of sufficient irritation of the respiratory tract to upset the normal breathing pattern. To determine the

which indicates the rate and volume of inspiration and expiration by recording the instantaneous pressure differential created by air flow through a fine mesh screen inserted in a breathing mask. The resistance to respiration of this device is negligible. A representative respiratory pattern of a subject exposed to 1000 parts of ammonia per 1,000,000 parts of air is presented in Figure 1. The upper record is the normal pattern, whereas the lower is the response following exposure to ammonia. It is evident that the breathing pattern is considerably altered. In general, exposure to an irritating gas such as ammonia resulted in coughing, reduction in the depth of inspiration and restraint of breathing. The subjects wished to avoid any further exposure. The breathing pattern after exposure to 10,000 parts of trichlorethylene per 1,000,000 parts of air (1 per cent by volume) is presented in Figure 2. Again, the upper record represents the normal curve for the subject, and the lower shows the response following exposure to trichlorethylene vapor. There is no essential difference between the two patterns

in fact, they could almost be superimposed except for the occurrence of a swallow during the third inspiration. This lack of any significant alteration in respiratory pattern was accompanied by a subjective willingness to continue the exposure, despite the rather strong sweet odor noted at this high concentration.

This failure to alter the breathing pattern and willingness to continue exposure to a concentration of a chlorinated hydrocarbon that approaches the anesthetic level is considered most significant, since far lower concentrations (500 parts per 1,000,000) are capable of producing organic damage following prolonged or repeated exposure.<sup>2</sup> It is not surprising, in the light of these observations, that dangerous exposures with the absorption of sufficient material to cause serious damage to the body may proceed without any awareness or recollection on the part of the patient. Such exposures will be avoided only if the patient is aware of their possible consequences, or if others who are aware of them make such exposure impossible.

At present the medical profession and industrial hygienists are well aware of the hazard associated with many solvents, and serious poisoning from these sources is occurring less and less frequently. For example, carbon disulfide and benzene no longer menace the health of workers as they did ten or twenty years ago, since the hazards are recognized and controlled.

New solvents and volatile chemicals, however, some of which may be capable of causing serious illness, are constantly being introduced in industry and to a lesser extent turned loose on an unsuspecting public. These illnesses will be attributed to the agents producing them only if the profession is alert to the possibility that a given illness has developed as a result of exposure to a toxic agent. Therefore, one should be aware of the general type of symptomatology and findings that may follow exposure to toxic gases or vapors, especially conditions developing after exposure to agents that are not unpleasant or irritating to breathe. The victim may fail to remember having been exposed and probably will not spontaneously disclose a history of exposure since, in his opinion, the disease he is suffering from is unrelated.

Disease of the liver or impairment of blood-cell formation has long been associated with solvent vapor exposures. The possibility of a toxic exposure is therefore usually thought of and investigated in patients with unexplained jaundice or with anemia or leukopenia. Many toxic vapor exposures may fail to give either of these reactions, however, resulting instead in the development of a nephritis that clinically is readily mistaken for ordinary glomerular nephritis. Since many physicians are not aware of the frequency of toxic nephritis due to single or multiple exposures, they may fail to inquire about previous exposure in a patient with

evidence of renal disease, when they would go to considerable lengths to determine such exposure in a patient with anemia or evidence of seriously impaired liver function. The failure to associate nephritis with toxic injury is rather surprising, since many cases of acute toxic nephritis have been reported following the inhalation of carbon tetrachloride.<sup>3-5</sup> Other agents are also capable of producing kidney damage. For example, an acute toxic nephritis recently occurred in a fifty-three-year-old shipping clerk who had undergone relatively brief but severe exposure to a solvent mixture containing 80 per cent toluene. This case was almost dismissed as one of acute glomerular nephritis, since the patient did not at first remember his exposure. The possibility of a toxic nephritis was considered when it was determined that he might have been exposed to carbon tetrachloride. When it was discovered that the solvent vapor to which he was exposed was 80 per cent toluene and 20 per cent ethyl acetate, the possible toxic nature of the kidney disease was almost dismissed, for toluene and ethyl acetate are not generally associated with the occurrence of nephritis. The facts that toluene exposure is capable of producing renal lesions in animals<sup>6</sup> and that the exposure was related to the onset of the nephritis and to the subsequent course of this illness were finally accepted as sufficient evidence to justify a diagnosis of toxic nephritis due to toluene. This case is cited to emphasize the fact that nephritis may occur as a result of serious exposure to toxic gases and vapors, even though the agent in question has not previously been recognized as being capable of inducing such a syndrome in man.

Such cases will be correctly diagnosed only if the medical profession considers the possibility of a toxic agent in cases that appear to be glomerular nephritis, obscure anemias or atypical liver disease. The possibility of any exposure to a toxic gas or vapor should be investigated in every such case, and if any suggestive history is elicited, the circumstances should be investigated thoroughly and the nature of the gas or vapor determined accurately. Finally, the fact that a given syndrome has not previously been reported as resulting from the agent in question does not rule out the possibility that such cases have occurred and gone unrecognized.

## MEDICAL PROGRESS

## RADIATION THERAPY

SAMUEL A. ROBINS, M.D.,\* BERNARD E. LEVINE, M.D.,† AND GEORGE WHITE, M.D.‡

BOSTON

THE basic principles of radiation therapy have undergone no radical changes during the last five years. The science of physics has contributed fresh means of accomplishing what the radiation therapist has always attempted: maximum selective destruction of the tumor with minimal damage to the normal tissues. These new contributions include apparatus for the generation of extremely high as well as extremely low voltages. The term "super-voltage," which once designated a charge of 400,000 volts, must now be applied to voltages in the range of 1,000,000 to 100,000,000. These powerful rays have the advantage of greater penetration, whereas the units of extremely low voltage have correspondingly low penetrability and are comparable in action to radium.

The development of the atomic bomb has provided a large supply of radioactive isotopes, formerly produced in small quantities by the cyclotron. These elements are now being used extensively as therapeutic agents, only time will evaluate their efficiency in the treatment of disease. The recent development of the betatron has initiated the experimental phases of therapy by means of high-energy electrons.

Large amounts of radiation are necessary for cancerocidal effect on tumors, notwithstanding damage to the skin and surrounding tissues. The injurious changes to structures in the path of the radiation become relatively unimportant as compared with the prime objective of tumor destruction. It is with this in mind that newer methods of radiation therapy are being evolved to accomplish maximum tumor destruction without ultimately damaging normal structures.<sup>1</sup> To approach this ideal, a proper perspective of tissue tumor sensitivity and the consideration of portals of treatment and physical factors are essential.

The previous methods of expressing the dosage in air or on the skin surface were both confusing and unsatisfactory. More recently the measurements of so-called "tumor dose" have given a more accurate description of the amount of radiation delivered to the center of the tumor. Quimby<sup>2</sup> and others<sup>3-5</sup> have provided many of the physical data for the compilation of these measurements. In

addition, radium dosages are now expressed in gamma roentgens ( $\gamma r$ ), giving a measurement comparable to that based on the roentgen (r), which is used in x-ray therapy. The earlier method of expressing doses in milligram or millicurie hours did not take into consideration the bulk of the tumor.

Tumor doses vary with different tissues. Warren<sup>6</sup> has noted variations in the response of tumors to irradiation. These tumors have been divided into the following groups: radiosensitive, radioresponsive and radioresistant. Warren<sup>7</sup> states "Radiosensitive tumors are not necessarily radiocurable. Often they are not, recurring in a resistant form after the initial regression." Certain radioresistant tumors, on the other hand, can be cured by adequate irradiation.

## BREAST

*Carcinoma*

Martin<sup>8</sup> states that only 25 per cent of all patients with carcinoma of the breast can hope for surgical cure. The remaining 75 per cent must therefore receive some form of radiation therapy.

The indications for radiation treatment of this disease are intimately associated with the criteria for operability. Radiation therapy is theoretically not indicated in cases that are operable. The criteria for operability have been fully described by Haagensen and Stout.<sup>9</sup> Borderline cases may be subjected to surgery, and some investigators<sup>10,11</sup> believe that these patients require postoperative therapy to ensure optimum results. The regions treated under these conditions include the immediate areas of lymph drainage—namely, the axilla, the supraclavicular and infraclavicular regions and the mediastinum.

X-ray therapy is the method of choice in the treatment of inoperable carcinoma of the breast.<sup>8,12</sup> Lenz<sup>13</sup> emphasizes the value of large cancerocidal doses and employs tumor doses as high as 6000 to 8000 r, which are given through multiple portals to the breast and axilla. When a dose of less than 5500 r was given, the tumor was not grossly eradicated. In his series of 48 patients treated with 6000 r or more, 10 were clinically free of disease five years later. Martin<sup>8</sup> treats inoperable breast neoplasms with interstitial radium-needle implantation to lessen the danger of pulmonary fibrosis, which may occur with roentgen therapy.

\*Professor of radiology, Tufts College Medical School.  
†Instructor in radiology, Tufts College Medical School.  
‡Instructor in radiology, Tufts College Medical School.

## UTERUS

*Carcinoma of the Fundus*

Carcinoma of the uterus can be treated by surgery, irradiation or a combination of both. Meigs<sup>13</sup> states, "There is no doubt that nearly all workers in this field believe that the combination treatment is most satisfactory." Corscaden<sup>14</sup> believes that the rate of five-year cures can be increased to 80 per cent with the combined method. Heyman and Benner<sup>15</sup> reported the largest series treated by irradiation alone. They gave their relative over-all cure rate as 64.9 per cent. The rate with radiation therapy alone depends on the uniform distribution of the radiation to the tumor. Many methods have been devised to obtain this effect.<sup>16-18</sup> Heyman et al.<sup>19</sup> pack the uterus with radium capsules, and their results show that excellent distribution is thus obtained.

The technic generally advocated is diagnostic curettage, followed by the immediate implantation of radium in cases of cancer.<sup>19-22</sup> The dose is carefully planned for each patient. Four to eight weeks later, surgical extirpation is performed in patients who are considered good surgical risks. If surgery is contraindicated curettage is repeated, and radium is reapplied if necessary.

Miller and Henderson<sup>22</sup> have reported 77 per cent five-year cures and 65 per cent ten-year cures from the combined method of treatment. Scheffey and his associates<sup>21</sup> give a five-year survival rate of 90 per cent for patients receiving adequate surgical treatment and irradiation by a planned technic.

*Benign Uterine Bleeding*

Radiation therapy for benign bleeding at the menopause must always be preceded by diagnostic curettage to rule out cancer. Irradiation does not replace surgical procedures, but it has a definite place in the treatment of menopausal uterine bleeding. Some of the indications for irradiation rather than surgery include poor surgical risks, refusal of major operation and pathologic states elsewhere in the body. Irradiation is contraindicated in myomas larger than the size of a grapefruit and extending out of the pelvis into the abdominal cavity, and in young patients for whom myomectomy is possible.<sup>23</sup> Radium is contraindicated in patients with submucous fibroids because necrosis may occur, causing persistent bleeding, x-ray therapy, however, may be used in these cases. Crossen and Crossen<sup>24</sup> have treated 526 cases of bleeding due to uterine myoma with radium, attaining successful results in 490 cases (93 per cent). Schmitz and Towne<sup>25</sup> have successfully treated 412 cases with either x-ray or radium. Of the many methods proposed for the treatment of benign uterine bleeding, radiation therapy is one of the most valuable because of the excellent results and the absence of mortality or morbidity.

*Carcinoma of the Cervix*

Carcinoma of the cervix is the most frequent malignant tumor of the female genital tract. Irradiation has one of its greatest fields of usefulness in this type of lesion. At the present time, there is a tendency to avoid accepted irradiation methods and to perform surgery. There is no doubt that surgery has a definite place in the therapy of carcinoma of the cervix in the very early lesions, with the carcinoma in situ or well localized. If the carcinoma is advanced, surgery becomes an extremely formidable procedure of doubtful value.

In recent years the earlier detection of carcinoma of the cervix has become possible with the vaginal smear,<sup>26</sup> and therefore treatment by either irradiation or surgery produces a much higher percentage of cures. Most patients, however, are first seen when the lesion is moderately advanced, and it is in these cases that irradiation is the treatment of choice. Anspach<sup>27</sup> states that in advanced lesions radical hysterectomy is a difficult procedure that can be performed only by a few highly trained and skillful gynecologists, whereas with irradiation there is practically no primary mortality and a minimum of morbidity. Irradiation can be used in the treatment of all carcinomas of the cervix regardless of their extent, with a large percentage of cures, in the earlier stages. It also effects good palliation in the very late stages, occasionally producing cures even in these cases. The results with supervoltage therapy in the advanced stages of the disease have not yet been fully evaluated.

Many methods of irradiation for carcinoma of the cervix have been advocated. The accepted procedure is to give intensive irradiation to the local lesion, usually by means of radium and protracted external x-radiation to the pelvis for disease in the parametrium. Most methods employ intrauterine and vaginal applicators. The intrauterine applicator is usually a tube containing several capsules of radium. The vaginal applicators include corks, plaques or colpostats containing radium capsules and placed against the cervix and in the lateral fornices. These provide effective intensive irradiation to the diseased cervix and parametrium.

Kaplan and Rosh<sup>28</sup> favor external irradiation followed by radium implantation and a subsequent course of external treatments. Elkins<sup>29</sup> and Bouslog<sup>30</sup> advocate intravaginal x-ray therapy combined with external therapy. Others<sup>31, 32</sup> use interstitial radium-needle implantation. Each method has its advantages.

Buschke and Cantril<sup>33</sup> do not follow a preconceived outline for treatment or a rigid technic. They write

Radiation therapy of cervical cancer has become one of the cornerstones of clinical radiation therapy. This supersedes surgery and is accepted as the superior procedure of choice because, in the overwhelming majority of cases, it accomplishes more with less risk if properly used.

## OVARY

There are many types of tumor of the ovary, both benign and malignant, but their classification is difficult because even today extremely little is known of their histogenesis. Mcigs<sup>11</sup> has outlined a classification according to the origin, whereas Cutler, Buschke and Cantrell<sup>12</sup> classify these tumors according to the type of proliferation. The malignant neoplasms are either solid or cystic. The latter are more frequent as well as relatively more radiosensitive than the former.

Most investigators agree that the proper treatment of carcinoma of the ovary is surgical extirpation of as much of the neoplastic tissue as possible, followed by an adequate course of radiation therapy. Kerr and Einstein<sup>13</sup> believe that postoperative irradiation should be given after the removal of as much neoplastic tissue as possible.

## SKIN

### Carcinoma

The local treatment of certain superficial skin diseases with radioactive phosphorus ( $P_{32}$ ) has been suggested by Low-Beer,<sup>14</sup> who soaked blotting paper in measured amounts of the solution and applied it to the skin surface, studying the effects of beta-particle radiation on the skin. Howes and Camiel,<sup>15</sup> Smathers<sup>16</sup> and others<sup>17,18</sup> discuss the value of low-voltage short-distance ("contact") x-ray therapy in the treatment of accessible superficial neoplasms. They believe that this method is of distinct advantage because the radiation is limited to the tumor and its immediate vicinity, the treatment time is short and the ultimate cosmetic result is excellent. Contact therapy is not applicable to bulky or inaccessible lesions. Strandqvist<sup>19</sup> and Ahlborn<sup>20</sup> have correlated the relation between total dosage and the treatment period and have charted the optimum tumor dosage for the desired number of divided doses over a given time. Hale and Holmes<sup>21</sup> compare the results obtained by the massive single-dose method and multiple treatments within the period of one week. They conclude that a dose of 2700 r given at one time produces essentially the same results as multiple doses totaling 4500 r delivered over a period of a week.

Warren<sup>22</sup> emphasizes the value of intensive therapy for skin cancer. He noted recurrences in the deeper layers, whereas the superficial portions healed with inadequate initial treatments. Young<sup>23</sup> points out that when recurrence follows either adequate or inadequate primary irradiation, radical surgical extirpation should be done.

## LYMPHOMAS

The experience of Reinhard et al.<sup>24</sup> at Washington University shows that radioactive phosphorus is ineffective for the lymphoma group of diseases. X-ray therapy is considered more desirable than

radioactive phosphorus and avoids the dangerous effects of that agent. Graff, Scott and Lawrence<sup>25</sup> made similar observations on experimental animals, demonstrating deleterious effects on the bone marrow and peripheral circulation with radioactive phosphorus. Any selective effect on tumor cells is greatly offset by the damage to the normal elements of the lymph and blood. The treatment of lymphomas is best carried out with x-rays at 200 kilovolts. The intensity and dosage vary according to the extent of treatment.<sup>26,27</sup> Desjardins<sup>28</sup> favors the use of moderately high voltages (around 140 kilovolts) and gives courses of treatment at intervals of several weeks.

When the disease is localized in a single small group of lymph nodes, the dosage should be in the range between 2000 and 3000 r.<sup>29</sup> Surgery has even been suggested for the freely movable, small mass of nodes.<sup>30</sup> Unfortunately, most patients are first seen in the advanced stages of the disease, when multiple groups of nodes are involved. When lymphoblastoma involves the spleen, mediastinum and lymph nodes, the treatment must be fitted to the individual patient. An acceptable rule is to give sufficient irradiation to cause complete regression of the nodes, with an additional 25 per cent for the residual microscopic tumor cells. This usually means a dose of 600 to 1800 r. Although larger doses can be administered, it is wiser to obtain a full effect with moderate doses. This procedure permits the administration of additional roentgenotherapy to the same areas later on when recurrences take place in other nodes. When a mass of nodes has been treated, incomplete disappearance does not mean failure of response. The replacement of disease by fibrosis often results in some residual enlargement. X-ray therapy is needless for enlarged fibrosed nodes and results in an expenditure of radiation that may be required in the event of future recurrence in the same regions. It must be recognized that the patient will become radioresistant, which usually indicates the terminal stages of the disease. Carefully planned irradiation often prolongs the period of radiosensitivity of the disease. The treatment of the acute forms of Hodgkin's disease is unsatisfactory at best. This consists of spray radiation or small amounts of irradiation over large surfaces of the body.

Nitrogen mustard has proved effective in isolated cases, but its use in routine therapy is considered unjustified.<sup>31</sup>

## PHARYNX, MOUTH AND SINUSES

### Larynx

The necessity of adequate cancerocidal doses for laryngeal carcinoma is stressed by Lenz,<sup>32</sup> who administers tumor doses varying from 5700 to 7000 r. In the presence of metastases to the lymph nodes, surgery is advocated when the nodes are freely movable. Otherwise, x-ray and radium are recom-

mended Arbuckle<sup>64</sup> states that the surgical removal of the thyroid cartilages allows large amounts of x-ray therapy to be given without danger of chondro-necrosis. Cutler<sup>65</sup> describes a method of concentrated radiotherapy, employed in the presence of radioresistant tumors of the larynx and pharynx. In this method the tumor is treated for a comparatively short time with large daily doses. This is in contrast to the Coutard method, in which small daily doses are given over a long period. Cutler<sup>66</sup> also diminishes the size of the field as treatment progresses, thus gaining the greatest concentration at the center of the tumor. The tumor doses vary from 5700 to 7700 r. The use of small fields, he states, is a definite advantage, allowing greater tumor doses with less effect on the surrounding normal tissues. This has also been pointed out by Blady and Chamberlain.<sup>67</sup>

The problem of surgery versus radiotherapy is discussed by Campbell,<sup>68</sup> who agrees that either form of treatment can be effective in the early stages of the disease. Radiation therapy is considered preferable in the early cases because the larynx is preserved, if proper and adequate radiation is given.<sup>66, 68</sup>

### *Nasopharynx*

Carcinoma of the nasopharynx is treated either by x-rays or a combination of x-rays and radium. Lenz<sup>69</sup> has shown five-year survival free of disease in 13 of 44 patients treated. It is interesting to note that 6 of these patients had lymphoepithelioma, which is an unusually radiosensitive tumor. Only 2 of these tumors were epitheliomas, slightly differentiated. Lenz considers the extent of disease and degree of bone involvement to be important factors in the prognosis. The presence of metastases is naturally of grave significance.

The use of radium therapy on lymphoid tissues of the nasopharynx was brought into prominence during World War II. The procedure was used successfully in the Air Forces to eradicate excess lymphoid tissues about the eustachian tubes.<sup>60-62</sup> Radium application and x-ray treatment of the lymphoid tissue of the nasopharynx are of value for deafness secondary to excess lymphoid tissues in the nasopharynx, infection of the middle ear and chronic otorrhea.<sup>63-65</sup>

### *Tongue*

Richards,<sup>66</sup> of Toronto, discusses radiotherapy in carcinoma of the tongue. He obtained three-year survival in 50 per cent of all cases treated. His treatment consists of external roentgen-ray therapy at 400 kilovolts, with a minimum tumor dose of 5500 r. When half the external dose has been given, intraoral radiation with 200 kilovolts is started and 3000 r is administered, so that the final tissue reaction is a summation of the external and intraoral irradiation. Residual carcinoma is

treated with interstitial radium, low-content (2-mg) needles being used.

### *Lip*

In carcinoma of the lip, the primary lesion may be controlled by irradiation or surgery, but the attack on metastatic lymph nodes in the neck is best carried out by radical dissection.<sup>67</sup> Routine prophylactic removal of the nodes is not recommended, but a careful follow-up study should be instituted. The early detection of nodes and prompt surgery give good results. When cervical metastases are too extensive for surgical removal, external irradiation together with radium seeds may be used. Schreiner and Christy<sup>68</sup> reported a series of 636 patients with cancer of the lip treated by x-rays or radium or both. They obtained an absolute cure rate of 58.9 per cent. The treatment of metastatic cervical lymph nodes by x-ray and radium therapy has been carried out with encouraging results by H. E. Martin<sup>69</sup> and C. L. Martin.<sup>70</sup>

### *Maxillary Sinuses*

Cancer of the maxillary sinuses still presents a challenge, because of failure to make an early diagnosis. Patients are often seen only after extension of the lesions into the surrounding bone structure. Valencia and Rosenthal<sup>71</sup> have accomplished eradication of epidermoid carcinoma in 2 of 3 cases reported, 1 patient surviving for three years and four months and the other for four years and two months.

### *MISCELLANEOUS CONDITIONS*

Munson and Munson<sup>72</sup> treated 20 patients with acute sinusitis with medium-voltage radiotherapy. Eleven patients had immediate relief after one treatment, and 4 after three treatments, 3 required five or six treatments. The authors conclude that small doses (100 to 150 r per treatment) give relief of pain in a large percentage of patients.

Roentgenotherapy in the atrophic arthritides relieves pain, spasm and stiffness according to Kuhns and Morrison.<sup>73</sup> Kersley,<sup>74</sup> writing of arthritis and rheumatism, asserts that probably no group of disease susceptible to x-radiation has been more neglected by the radiotherapist. Hemphill and Reeves<sup>75</sup> show that the best results in Marie-Strümpell disease can be expected if x-ray therapy is begun while there is still active granulation and before ankylosis has set in. They obtain reduction of pain and stiffness, gain in weight, decrease in sedimentation rate and a return to gainful occupation in a large proportion of patients.

Rapid and dramatic relief of the agonizing pain of acute bursitis has been demonstrated by Brewer and Zink,<sup>76</sup> who advocate a single large dose of 300 r with 200 kilovolt therapy. Others<sup>77, 78</sup> recommend smaller multiple doses. Only fair results have

been obtained with the chronic buristides, however, with relief reported in 30 to 40 per cent of cases 74-78

Robbins<sup>79</sup> demonstrated no ill effects and fairly long remission with multiple small doses to large areas of the body in the treatment of polycythemia vera. Hall et al<sup>80</sup> report their results with radioactive phosphorus in this disease. They observed remissions lasting from nine to twenty-six months. An excellent review of treatment results with radioactive phosphorus is presented by Reinhard and his co-workers.<sup>81</sup> The only encouraging results were found in the treatment of polycythemia vera. Other blood dyscrasias and lymphomas were more difficult to control than by roentgenotherapy.

In the treatment of acute infections, Kelly<sup>82</sup> points out that fairly large areas should be irradiated, including some normal tissue around the infection. He also notes that the sulfonamides alter or inhibit the effect of x-rays and points out that the two types of therapy should not be combined, since the combination of the therapeutic agents produces a high morbidity.

BENJAMIN CASTLEMAN, M.D., *Associate Editor*

EDITH E. PARRIS, *Assistant Editor*

### CASE 34021

#### PRESENTATION OF CASE

A seventy-eight-year-old housewife entered the hospital with the chief complaint of difficulty in swallowing.

During the two years preceding admission the patient was bothered by a chronic nonproductive cough that went through cycles of exacerbation and remission. She denied hemoptysis and night sweats. About a year before admission she was put on a diet for hypertension and lost 20 pounds in five or six months. Following this, however, she continued to lose another 20 pounds, and lost her appetite. About three months before admission she became hoarse, the cough became coarse, and she noted weakness and fatigue. She had no difficulty in swallowing solid food, but liquids regurgitated into the nose. She denied nausea, vomiting, indigestion, abdominal pain or any abnormality of bowel habit.

Ten years before admission the patient had had a radical mastectomy for carcinoma simplex, with a metastasis to one of ten regional lymph nodes examined. Six years before admission a lymph node had been excised from the submaxillary region, and a diagnosis of malignant lymphoma, follicular type, was made. The patient had had known high blood pressure for many years and moderate dyspnea and orthopnea for several years. There was no edema of the ankles and no episodes of congestive failure.

Physical examination revealed a pale, obese, flabby, deaf woman in slight respiratory distress. The right breast was absent, and the operative wound was well healed, without evidence of recurrence. No lymph nodes were palpable in the neck or in the axillae. The chest was clear. The heart was questionably enlarged, with a Grade I apical diastolic murmur. The abdomen was soft, no organs or masses were palpable.

The temperature, pulse and respiratory rates were normal. The blood pressure was 220 systolic, 110 diastolic.

Examination of the blood disclosed a red-cell count of 4,300,000 with a hemoglobin of 14 gm, and a white-cell count of 7200, with 64 per cent neutrophils, 34 per cent large lymphocytes and 2 per cent monocytes. The nonprotein nitrogen, the total protein and the blood chloride were within normal limits. An electrocardiogram showed right bundle-branch block. An x-ray film of the chest revealed no abnormal shadows in the lungs, ribs or pleura. There was a streak of atelectasis in the right costophrenic angle. With the aid of a barium swallow a pressure defect was demonstrated in the esophagus, pushing it forward as well as narrowing the lumen. This was at the left of the aortic arch. A similar defect was demonstrated on the anterior margin just below the carina (Fig. 1).

On the fourth hospital day esophagoscopy was performed. An area of narrowing was found, but it was possible to pass the instrument beyond the point of obstruction and careful inspection showed no lesion of the mucosa.

X-ray therapy was begun, at first 200 and then 300 r to the mediastinum daily, followed by alternating anterior and posterior portals.

The patient did not do well. Cough, dyspnea and dysphagia continued. On the second day after esophagoscopy the temperature spiked to 101°F, and a chest film showed a markedly elevated right leaf of the diaphragm and several streaks of atelectasis about the dome. On the twenty-first hospital day a gastrostomy was done, but the patient was not benefited appreciably. The temperature from

the third postoperative day on was elevated, going as high as 102.6°F, and the operative wound broke down around the gastrostomy tube. The patient gradually lapsed into coma and died quietly on the eighth postoperative day. The chest had remained clear until the very end.

### DIFFERENTIAL DIAGNOSIS

**DR. CARROLL C. MILLER** We have two lines of attack in making the diagnosis in a case of this sort. The first is anatomic, to determine whether the mass that evidently accounts for the difficulty in swallowing was intraluminal, extraluminal or extrinsic to the esophagus. The other line concerns the relative probability of the three suggested pathological diagnoses—carcinoma of the esophagus, which, particularly in this age group, is most common, or metastasis from one of the malignant tumors already demonstrated, lymphoma or carcinoma of the breast.

May I see the x-ray films?

**DR. STANLEY M. WYMAN** The heart is prominent toward the left in the region of the left ventricle. The aortic arch is obviously tortuous, and there is tortuosity in the descending aorta, where it can be faintly seen behind the heart. There is a streak of atelectasis at the right base. Pressure on the esophagus is demonstrable on the right posterior aspect just below the level of the arch of the aorta in these two films and also on the spot film. A second area of pressure on the esophagus is seen lower down anteriorly on the left. These areas show no evidence of intrinsic involvement of the esophagus and appear to be pressing upon rather than arising in the esophagus.

**DR. MILLER** I assume that there is no fluoroscopic report to demonstrate motion of the right leaf of the diaphragm. The patient was perhaps too ill at this point to be fluoroscoped.

**DR. WYMAN** I believe that the patient was fluoroscoped, because of the spot films, but I do not know what the fluoroscopist said about the diaphragm.

**DR. MILLER** To go back to the first category, I think that we can dismiss an intraluminal growth as a cause of the obstruction. Two methods of examination are in agreement on this point: the swallow of barium revealed a clearly outlined mucosal pattern of the esophagus, and esophagoscopy showed no evidence of mucosal destruction.

So far as an intramural growth is concerned, we usually see a more definite bulging, a distortion of the mucosal pattern, and with it a mass of solid consistence outside the esophagus. But, again, it is not always definitely possible to see an intramural mass by x-ray examination.

Concerning the third group, the extrinsic masses, we can get only such information as the x-ray examination provided us with here. Usually, however, there are other data that help in making such

a decision, especially the presence of mediastinal lymph nodes. Dr. Wyman did not mention the presence of mediastinal nodes in these films. I do not see them, and I do not believe they are there.

**DR. WYMAN** I cannot identify them *per se*, unless the esophageal pressure defects are from enlarged lymph nodes.

**DR. MILLER** Before we discuss the more likely possibility one should mention other extrinsic causes for compression of the esophagus. The two more common ones are aneurysm and a benign

FIGURE 1

nontumorous obstruction from enlarged lymph nodes. I am thinking particularly of tuberculosis. We have had several cases of tuberculosis in this hospital with esophageal obstruction because of tuberculous involvement of mediastinal lymph nodes. I do not believe that this patient had an aneurysm; the x-ray studies do not show evidence of it. The symptom of hoarseness immediately makes one think of involvement of the recurrent laryngeal nerve, which is frequently seen with aneurysm. We do not know which nerve was involved. There was no mention of which cord was paralyzed. Because of the high diaphragm that subsequently developed I should guess that the right phrenic nerve became involved, and consequently paralysis of the right recurrent laryngeal nerve is more probable. I see no evidence of aneurysm of the right

subclavian artery or great vessels at the base of the heart

We have no further evidence of tuberculosis, although this is not necessarily required in making such a diagnosis. Cases of tuberculous adenitis may not have demonstrable evidence of tuberculosis in the chest or elsewhere. Having dismissed the most common causes of extrinsic pressure and having dismissed the diagnosis of epidermoid carcinoma of the esophagus, I might also dismiss adenocarcinoma of the esophagus because it is relatively rare to find adenoid tissue in the esophagus—at this level, particularly—not visible at esophagoscopy.

We can thus continue to a discussion of the likelihood of lymphoma or metastatic carcinoma, which brings us down to a more or less statistical discussion. The patient had had carcinoma of the breast ten years previously. Although the survival of patients with metastases from carcinoma of the breast is definitely short, in the region of 30 per cent five-year cures, we have been seeing what I would call a considerable number of late cases of metastatic carcinoma from the breast anywhere from six to twelve years postoperatively. These patients have no symptoms whatsoever of metastatic disease. In reference to the exact symptoms that this patient had, we find a common one, frequently the first that bothers the patient with this disease—namely, cough. For two years she had had non-productive cough, evidently a general irritative phenomenon around either the trachea or major bronchi. The x-ray studies in this hospital showed no evidence of pulmonary disease in this patient. We must assume that she had a more local irritative factor. These patients who first begin to cough years after a radical mastectomy for carcinoma have a nonproductive cough, and they have increasing dyspnea as the mediastinal lymph nodes encroach more and more on the major bronchial system. Subsequently, they have collapse of various parts of the lung because of unsatisfactory drainage from the bronchial tree. So much for carcinoma. Another red herring is the presence of malignant lymphoma in this history—one solitary focus removed six years previously from the submaxillary gland. Do we know if she ever had evidence of recurrence of this tumor?

DR TRACY B MALLORY The patient was followed at relatively frequent intervals at the Huntington Clinic, and no evidence of recurrent disease was found.

DR MILLER It is said that malignant lymphoma may remain quiescent for many years. One author quotes the average duration of life with malignant lymphoma of the follicular type as four years, but various others list it as six to fourteen years. The diversity of lymphomatous involvement in the body is well known, and there may be such disease in the mediastinal nodes to account for this difficulty.

I believe that I must make a diagnosis of metastatic carcinoma of the breast. The patient had progressive weight loss. This is frequently found in the absence of symptoms or definite physical demonstration of metastatic disease. She had an invasive type of tumor. I say that because she must have had nerve palsy of both the recurrent laryngeal nerve and the phrenic nerve. She had progressive disturbance of the esophagus and the bronchial system, with increasing dysphagia and increasing tracheobronchial irritation. The difficulty in swallowing liquids, with no difficulty in swallowing solid food, is also suggestive of nerve injury.

DR MALLORY Would anyone care to consider the possibility of primary bronchiogenic carcinoma?

DR DONALD S KING I do not see how it could be ruled out.

DR MILLER Certainly the sequence of events is compatible with that diagnosis. Multiple malignant tumors in the same patient are being more and more frequently seen. This patient would then have had three different tumors.

#### CLINICAL DIAGNOSIS

Metastatic carcinoma of mediastinal lymph nodes

#### DR MILLER'S DIAGNOSIS

Metastatic carcinoma from breast to mediastinal lymph nodes, involving esophagus and right main bronchus

#### ANATOMICAL DIAGNOSES

(Carcinoma of breast)

*Metastases to mediastinal lymph nodes involving esophagus and right main bronchus*

Metastases to liver

#### PATHOLOGICAL DISCUSSION

DR MALLORY The section from the submaxillary region on which the diagnosis of giant follicular lymphoma was made a few years ago was shown to me before I knew the history and the outcome of this case, and I disagreed with the diagnosis, reporting it as inflammatory hyperplasia. At autopsy we found a very scirrhous tumor occupying the region of the mediastinal lymph nodes, which were largely unrecognizable. The tumor had extended posteriorly into the wall of the esophagus and anteriorly into the wall of the right bronchus. There was extensive involvement of the bronchial mucosa. Therefore, from the gross evidence it could have been primary bronchiogenic carcinoma. We believed that we could rule out a primary tumor of the esophagus.

Microscopical sections showed a scirrhous adenocarcinoma, and though not absolutely conclusive were much more suggestive of a metastatic lesion from the breast than of a primary bronchial tumor. Part of the swallowing difficulty was due to a retropleural abscess above the point of tumor involvement of the esophagus. There were some

metastatic nodules in the liver. There was no evidence of lymphoma at autopsy.

DR. MILLER: What do you suppose the duration of the abscess was?

DR. MALLORY: A number of days or perhaps a couple of weeks — a very acute lesion, I believe.

## CASE 34022

### PRESENTATION OF CASE

A fifty-one-year-old Italian electrical worker was admitted to the hospital because of hemoptysis.

Two years previously, he had an upper respiratory illness characterized by cough, sweating and pain in the right lower portion of the chest on breathing. He had not worked for several weeks, but did not remain in bed. Recovery from this episode was apparently complete, but eight months later a similar episode occurred. At that time the cough was productive of considerable whitish sputum. A bronchoscopy was performed, but no diagnosis was given to the patient. Three months before entry, he again began to feel "bad all over." The cough returned, persisting throughout the day, and was productive of a small amount of blood-tinged sputum, which was raised mainly in the mornings. He had been anorexic, with a weight loss of 7 pounds, and had been unable to work for three months.

Physical examination revealed that the lower third of the right portion of the chest posteriorly was dull to percussion, with diminished breath sounds heard over the area. The prostate was regular, firm and enlarged to twice the normal size.

The temperature, pulse and respirations were normal. The blood pressure was 125 systolic, 80 diastolic.

Examination of the blood disclosed a hemoglobin of 14.6 gm and a white-cell count of 10,600, with 71 per cent neutrophils, urinalysis was negative. A blood Hinton test was negative. Five sputum examinations and one guinea-pig inoculation were negative for tuberculosis.

An x-ray film of the chest showed a segmental area of atelectasis posteromedially in the right lower lobe. The adjacent portions of the lower lobe close to the abnormal area were somewhat emphysematous. There were small blebs in both apices. The heart was displaced slightly to the right. A bronchogram revealed incomplete visualization of the right middle-lobe bronchus, and the middle lobe appeared slightly diminished in size. The bronchi to the anterior basal segment and dorsal division of the right lower lobe appeared normal, the bronchi leading to the atelectatic area were not filled. Laryngoscopy and bronchoscopy disclosed considerable thick yellowish-green secretion in the larynx and trachea. The right bronchial tree was reddened throughout and contained thick yellowish-green secretion. The

right upper-lobe orifice was reddened, and the bronchus displaced downward. The stem bronchus and the middle-lobe orifice were also reddened. The lower-lobe bronchus was red, edematous and displaced to the right, with considerable thick secretion and edema. No adenoma or foreign body was visible. The remainder of the examination was negative.

On the fourteenth hospital day an operation was performed.

### DIFFERENTIAL DIAGNOSIS

DR. LAMAR SOUTTER: The general picture is that of a middle-aged electrical worker with a brief history of pulmonary disease — that is, brief compared to many stories of chronic pulmonary infection that we see. There were three episodes of illness: one, two years before entry, one fourteen months before entry, and finally a third. The first two illnesses were not of very long duration, and recovery was apparently quite complete. They seemed to be infectious in nature. I do not receive the impression of a patient with steadily progressive disease, such as might be expected with tumor, but rather a picture of two attacks of pneumonitis with sputum, and probably an elevated temperature, although that is not stated. He did have pain in the right lower portion of the chest, and hemoptysis, on one occasion. The third sickness was of much longer and more serious extent. The patient when he came in had been unable to work for three months. On arrival at the hospital he gave the appearance of having chronic pulmonary infection. He did not have a high temperature, although he had a slight elevation of the white-cell count. He was raising sputum, and he had morning sweats, malaise, anorexia and weight loss.

What would be the source of a chronic infection in a man of this age coming into the hospital with this brief history? In looking back on the first two episodes, the possibility of septic infarction arises, followed by abscess formation, the abscess healing but perhaps breaking down and healing and breaking down again. On the other hand one wonders about that when presented with the x-ray picture showing an area of increased density without the fluid level that one might expect in an abscess of some two years' standing, which had been active for at least three months prior to entry. We do have the idea, however, that although an abscess was unlikely there was probably some bronchial obstruction because atelectasis was observed by x-ray examination.

I wonder if Dr. Wyman will show the x-ray films at this point?

DR. STANLEY M. WYMAN: The only available films are those taken after the introduction of lipiodol. The left anterior oblique view shows best the area of atelectasis, in the posterior medial

segment of the right lower lobe. The bronchi to this region are incompletely filled.

DR SOUTTER: Does the incomplete filling suggest difficulty in injecting the dye or an obstruction of the bronchi?

DR WYMAN: There is some obstruction of the flow of lipiodol to that region. I can see no definitely abnormal bronchi on the right side. The left side appears perfectly normal.

DR SOUTTER: The information that is given to us by the x-ray pictures is one of atelectasis with possible partial obstruction to the bronchus leading to the atelectatic area. It is probably right to assume that the chronic infection had its origin in this collapsed area. What should we regard as the etiology of this collapse? Obstruction, partial or complete, in a bronchus can come from extrinsic pressure, from cicatricial narrowing of the bronchus secondary to infection or from obstruction inside the bronchus by a mucous plug, by a foreign body, by an adenoma or by a carcinoma.

What information do we get from bronchoscopy? It confirmed the evidence of infection in the right side of the lung. The sputum was described as thick and greenish, it was not described as foul. We can assume that the aspirated secretion came from the right lower lobe by the description of edema in this bronchus. The reddening elsewhere reflects the severity of the infection rather than an extension of the disease process.

DR EDWARD B. BENEDICT: In the bronchoscopic report I mentioned that the breath was very foul.

DR SOUTTER: There is some evidence, then, of a possible putrid abscess, since the breath was foul, and that is something that we should consider.

What about infection causing obstruction of the bronchus? The x-ray picture is not one of a true bronchiectasis due to a mixed infection. We do not have a report of the sputum culture. We cannot tell, of course, whether the lipiodol failed to enter the bronchus or whether there was some bronchiectatic obstruction. This is not the typical picture of long-standing pulmonary infection or the characteristic story of bronchiectasis that goes back to childhood. If present from childhood the disease is usually manifested at an earlier age. So we may assume that whatever caused the trouble was probably more recent, and that bronchiectasis on the basis of chronic infection is probably not a great likelihood in this case.

What about bronchiectasis on the basis of tuberculosis? Has that been completely eliminated by the sputum studies or the location of the atelectasis? I do not believe that it has been completely eliminated. With the report of thick, greenish, foul sputum, which was negative on bacteriologic study, however, it is probably not very likely.

We should consider actinomycosis, blastomycosis or some fungous infection. The position is right for abscess formation due to these types of organisms.

These abscesses are usually in the lower lobes when they occur. On the other hand, the causative organisms are generally readily identifiable by sputum examination. In actinomycosis the sulfur granules are often coughed up. We have seen an occasional case in which these organisms did not appear in the sputum, and not until after the lung tissue had been removed was it obvious that actinomycotic abscess was the correct diagnosis.

What about the possibility of a foreign body plugging the bronchus? That is not likely in an adult without a history of aspirating some object. In a child such a diagnosis could be seriously considered without such a history, but not in an adult. Furthermore, we might see a radiopaque foreign body by x-ray study.

That brings us, then, to the consideration of whether or not this could have been a tumor of some sort. We think first of course of an adenoma—or, in other words, a benign tumor arising in a bronchus. Most adenomas arise in the main bronchus on one side or in a branch of it. Very seldom do they occur so far peripherally as not to be readily observed by bronchoscopy. They usually occur in people younger than this man. The patient nearly always gives a history of chronic infection or hemoptysis before coming into the hospital.

Could this have been a metastatic carcinoma? A metastatic carcinoma usually appears as a round shadow in the lung periphery. It will not cause collapse of a lung segment until it has grown large enough to press on a bronchus. The only organ suggested by the story as a source of a primary tumor was the prostate. Although the prostate was enlarged to twice the normal size, it was smooth and not nodular. Furthermore, the history was not that of metastatic disease.

Other diseases such as sarcoid and lymphoma should be mentioned. They seem unlikely because in those diseases the lesions are usually multiple and give a different x-ray appearance, atelectasis being more apt to occur very late as they progress.

Therefore we come down to bronchiogenic carcinoma. Adenocarcinoma is less common than the epidermoid type. What is the possibility of an epidermoid carcinoma with partial or complete bronchial obstruction, dilatation of the bronchus distal to this with abscesses and a great deal of inflammation? I think that the chances are very good. The patient was in the right age group for cancer although younger than many patients with bronchiogenic carcinoma whom we see. This tumor does not always occur at the hilus. It can occur in bronchial tissue far out in the periphery of the lung. It is nearly always attended by atelectasis—so much so that I feel strongly that atelectasis in a patient in this age group, without evidence of other causative disease, should be regarded as secondary to bronchiogenic carcinoma. What about the emphysematous blebs and the bloody sputum?

I do not believe that the blebs were of any importance in this man. Blood-tinged sputum can occur in a great number of diseases and is not of much help diagnostically.

I shall hazard a diagnosis of carcinoma of the bronchus leading to the collapsed area of the lung and atelectasis, with chronic infection and perhaps small abscesses in that segment of the lung.

DR. DONALD S. KING: I cannot remember any case with cancer in a bronchus with a negative bronchoscopy, can you, Dr. Benedict?

DR. BENEDICT: No, I cannot, and my impression was that the bronchoscopy was definitely consistent with bronchiectasis—that is, a hemorrhagic bronchiectasis with a red, edematous mucosa that we frequently see in straight bronchiectasis causing enough bronchial obstruction to give this picture.

DR. KING: That would be my bet. I was trying to think whether this was one of Dr. Sweet's pneumonitis cases and whether one would find cholesterol. I would bet that it was not that type of disease, but an area of bronchiectasis with abscess, which usually does not give so much cholesterol as these so-called pneumonitis cases. We have not a plain x-ray film to see if the abscess looked as much like tumor as those in Dr. Sweet's cases did.

DR. JOHN G. SCANNELL: This man had had a previous bronchogram six to eight months prior to entry here that showed diffuse bronchiectasis of the right lower lobe and also questionable involvement of the right middle lobe. We repeated this for our own information partially, and our feeling was that he had bronchiectasis in the major portion of the lower lobe. It improved for a period as judged by x-ray study, but we were puzzled by the segmental nature of the process. We debated whether or not to let the patient go home and get the bronchus in better shape and come back for a surgical procedure. In view of the segmental nature, Dr. Churchill thought that we should proceed with operation. With the data we had and with a man in this age group a lobectomy was done (Fig. 1). The pleura as I remember it was involved. The lobectomy was carried out without undue difficulty. The gross appearance of the lung was that of recurrent infection. The lower lobe showed the gross appearance of bronchiectasis. We did not open the bronchi at operation.

#### CLINICAL DIAGNOSIS

Bronchiectasis, right lower lobe

#### DR. SOUTTER'S DIAGNOSES

Epidermoid carcinoma of branch of right lower-lobe bronchus  
Secondary atelectasis and infection

#### ANATOMICAL DIAGNOSES

*Epidermoid carcinoma of bronchus of right lower lobe*  
*Bronchiectasis*  
*Pneumonitis, chronic*

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: When the lung was sectioned in the laboratory we found the bronchi-

FIGURE 1

ectasis, but it was obvious that there was also slight but definite nodularity of the mucous membrane of the bronchus. Sections from that area showed an epidermoid carcinoma. The surrounding lung tissue showed chronic pneumonitis of the secondary suppurative type seen with bronchiectasis.

segment of the right lower lobe. The bronchi to this region are incompletely filled.

DR SOUTTER: Does the incomplete filling suggest difficulty in injecting the dye or an obstruction of the bronchi?

DR WYMAN: There is some obstruction of the flow of lipiodol to that region. I can see no definitely abnormal bronchi on the right side. The left side appears perfectly normal.

DR SOUTTER: The information that is given to us by the x-ray pictures is one of atelectasis with possible partial obstruction to the bronchus leading to the atelectatic area. It is probably right to assume that the chronic infection had its origin in this collapsed area. What should we regard as the etiology of this collapse? Obstruction, partial or complete, in a bronchus can come from extrinsic pressure, from cicatricial narrowing of the bronchus secondary to infection or from obstruction inside the bronchus by a mucous plug, by a foreign body, by an adenoma or by a carcinoma.

What information do we get from bronchoscopy? It confirmed the evidence of infection in the right side of the lung. The sputum was described as thick and greenish, it was not described as foul. #### EATING OUT IN SAFETY

AN ARTICLE in the Massachusetts Department of Public Health column in this issue of the *Journal* gives information that makes us wonder why even more illness does not result from the increasing American custom of eating out, for surveys conducted by the Massachusetts Department of Public Health during the last two years disclose that the sanitary conditions in restaurants and other eating places in the Commonwealth are far from ideal.

Public opinion, apparently, is doing a very satisfactory job of policing the conditions in the front of such establishments, and places that do not provide clean and cheerful surroundings fail to gain patronage. Unfortunately, the public usually knows very little of what is going on behind the scenes, where the danger usually lurks, and in communities where there are no regular inspections by health-department personnel slipshod methods quickly develop.

The public, however, has the right to expect that health agencies will take the responsibility for seeing that what happens behind the scenes is not endangering health, on the other hand, the health agency can expect the community to provide sufficient well trained personnel so that this responsibility can be satisfactorily met. In many municipalities the remuneration available for health-department employees is not sufficient to obtain

the services of an inspector who knows enough about restaurant sanitation to do a satisfactory inspection job. The Massachusetts Department of Public Health with its small staff of sanitarians can only attempt to assist local inspectors in learning to make satisfactory inspections so that owners of eating places may be informed of what is expected of them.

It is not surprising that some of the conditions exist because even owners have had little opportunity to learn the importance of many of the procedures usually demanded in restaurant sanitation regulations. Owners are usually co-operative in improving conditions when the faults are called to their attention.

Physicians, as important citizens of the community, can exert a forceful influence on this particular problem if they will inform themselves regarding conditions in their own communities and speak a word to the proper public officials.

#### MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

##### RESTAURANT SANITATION

Hardly a week goes by in Massachusetts that we do not hear of an outbreak of disease following a church, school or lodge banquet, or a meal served at some large cafeteria or a restaurant. Unfortunately, most of the outbreaks due to contaminated food in restaurants are never officially reported. That such outbreaks do originate in restaurants is evidenced by the fact that various members of the Department bear about them, sometimes weeks or even months after they occur.

Most outbreaks could be prevented if three important items of sanitation were strictly observed: if persons handling food took more interest in personal hygiene, and particularly if they kept their hands clean, if all foods favorable to the growth of bacteria were properly refrigerated, and if multi-use utensils employed in the preparation or serving of food and drink were thoroughly cleaned and effectively sanitized immediately after the day's operation, or more frequently if necessary.

Other items of sanitation such as cleaning and bactericidal treatment of eating and drinking facilities, structural facilities and waste disposal are important, but the experience in Massachusetts is that the three items mentioned above are the most important ones.

The Department of Public Health, through the Division of Food and Drugs, has authority to in-

ment (this has several advantages — it helps to make a large enough population unit to make a department economically possible and efficient and tends to equalize the differences in wealth between urban and rural areas, and the city, which depends upon its surrounding rural areas for much of its wealth and trade, should thus also be prepared to co-operate in providing basic health services required in common by all the people of the composite community), and in counties with less than 50,000 population, two or more that form a natural trade and transportation area should pool their resources to form a district health unit with at least this minimum population — more adequate services for the same amount of per capita expenditures can be achieved with an even larger population than the minimum, such as 100,000 or more, if no part of the population of the area is more than forty miles from the central point at which the health department would be located

The following seven steps are necessary to build a community temple of health the state health department should have a workable plan whereby local health service can be carried out for every community in the state, a state-wide citizens' health committee that includes representatives of voluntary and citizen agencies and that is approved by the governor should be organized, if it does not already exist there should be clear-cut legislation providing for county, city-county or district boards of health, the legislation should include authorization for personnel and salaries, the legislation should also include specific authorization for tax support of the local health department, and there should be agreement among state and local authorities concerning local, state and federal sources of tax support, a program of recruiting and training personnel, including in-service training, must be carried out, and a local community council must follow through to obtain local tax support and to keep the department alert, once it is organized

LOCATION OF TUMOR DIAGNOSTIC SERVICE

As announced in an earlier issue of the *Journal*, the Diagnostic Laboratory of the Massachusetts Department of Public Health is now located at 281 South Street, Jamaica Plain, with the Wassermann Laboratory (JA 4-1232) on the first floor and the Bacteriological Laboratory (JA 4-5440) on the second floor

Misunderstandings, however, have apparently occurred regarding the location of the Tumor Diagnostic Service This service is still located at the Harvard Medical School, 25 Shattuck Street,

Boston (LO 6-2380) The outfits for shipping specimens, however, are still to be ordered from the Diagnostic Laboratory, 281 South Street, Jamaica Plain

MISCELLANY

BORDEN AWARD

The American Academy of Pediatrics recently announced that the Borden Award for "outstanding research in the nutrition of infants and children" has been given to Dr Grover F Powers, chairman of the Department of Pediatrics at Yale University School of Medicine. The award, which is administered by seven professional and scientific associations, was established in 1936 to recognize and encourage outstanding research achievements in the food industry and related fields

Dr Powers is president of the American Pediatric Society and a former president of the New England Pediatric Society

AMERICAN HOSPITAL ASSOCIATION

Eighteen institutes for hospital administrative personnel, offering intensive hospital service education in short courses, have been scheduled for 1948 by the American Hospital Association Designed to provide basic material and information, together with a discussion of current problems, the institutes will feature authoritative faculties and are located so that hospitals in all parts of the country may participate Further information on the institute schedule will shortly be made available to Association members in a special brochure

In addition to the following, tentative plans have been made for an institute on pharmacy in May in the East, a November institute on hospital purchasing, also in the East, and a Middle Western institute on nurse anesthetists in December

DATE	PLACE	CITY	SUBJECT
January 12-16	Soreoo Hotel	St Petersburg Florida	Dietetics
January 26-30	Wisconsin Hotel	Milwaukee Wisconsin	Medical records
February 23-25*	Grady Hotel	Atlanta, Georgia	Personnel
March 1-5	Drake Hotel	Chicago Illinois	Nursing
March 8-12	Providence Hospital Auditorium	Oakland, California	Nurse anesthetists
April 12-13*	Continental Hotel	Kansas City, Missouri	Dietetics
April 26-30	Drake Hotel	Chicago Illinois	Housekeeping
April 19-23	Buck Hill Falls Inn	Buck Hill Falls, Pennsylvania	Dietetics
May 17-21	Shirley Savoy Hotel	Denver, Colorado	Purchasing
May 24-28	Knickerbocker Hotel	Chicago, Illinois	Operating engineers
May 31-June 4	Westminster Choir College	Princeton New Jersey	Public relations
June 8-12	Duke Hospital	Durham North Carolina	Medical records
July 19-23	Penn Sheraton Hotel	Philadelphia, Pennsylvania	Laundry
July 26-30	Drake Hotel	Chicago, Illinois	Accounting
October 4-8	Hotel New Yorker	New York City	Personnel
November 15-19	Wiltroo Hotel and Municipal Auditorium	Long Beach, California	Accounting
December 6-8*	Roosevelt Hotel	New Orleans, Louisiana	Public relations
December 6-10	Wardman Park Hotel	Washington, D C	Hospital planning

\*Short institutes.

THE AMERICAN SOCIETY OF ANESTHESIOLOGISTS, INC

At the annual meeting of The American Society of Anesthesiologists held in New York City on December 4, 5, and 6, 1947, John Abajian, M D, of the University of Vermont College of Medicine, Burlington, Vermont, was elected to the Board of Directors of that society

## BOOK REVIEWS

*Osteotomy of the Long Bones* By Henry Milch M.D. 8<sup>th</sup>, cloth, 294 pp with 181 illustrations. Springfield Illinois Charles C Thomas 1947 \$6.75

Dr. Milch, after long study and experience, has changed the so-considered simple osteotomy to a surgical procedure of refinement and mathematical exactness. The various types of osteotomy, local, torsional, transpositional and angulation, are discussed. He shows how varying lengthening and shortening can be obtained by placing the osteotomy site higher up or lower down upon the shaft of the bone and also by varying the amount of angulation at the osteotomy. This can be figured readily by trigonometric formulas. In the femur the greatest increase in length is accomplished by complete valgus of the femoral neck. For the solution of these complex problems about the head and neck of the femur the author has devised a movable frame to show movement of the pelvis and femur and the length of the weight bearing line after osteotomy and abduction. This frame he calls an "osteometer". He discusses the application of osteotomy to ununited fractures of the femoral neck, osteoarthritis and tuberculosis. He should be commended for giving so clear and sensible a discussion of osteotomy. Every orthopedic surgeon will profit from reading this book.

*Textbook of the Nervous System. A foundation for clinical neurology.* By H. Chandler Elliott M.A. Ph.D. With an introduction by Wilder Penfield M.D. 4<sup>th</sup>, cloth 384 pp with 158 illustrations and an atlas. Philadelphia J. B. Lippincott Company 1947 \$8.00

This anatomic study of the nervous system incorporates a number of new principles, all of them of distinctive importance. To acquaint the medical student with the complicated anatomy of the whole nervous system the author has divided the book into two parts. The first which contains a simple outline covers about a hundred pages, giving the essentials and is illustrated with diagrams often printed in two colors the field covered is that needed by every medical student. In the second part, the anatomy and the more simple function of the nervous system are taken up in more detail, corresponding to the needs of an advanced student or one who is going to practice clinical neurology. With the details of the gross anatomy are many diagrams illustrating the text. These are line drawings, giving so extremely clear concept of structural anatomy particularly of the brain. They are by far the best diagrams known to the reviewer, accompanying them is a text of equal value. In addition, the author has provided, in the appendixes a list of the principal terms used in anatomy making particularly clear those of Latin and Greek derivation. A bibliography adds to the value of the work, and by a system of single and double stars papers and books of particular importance are emphasized. Furthermore the book is accompanied by an atlas showing the actual appearance of the brain as the result of a surgical operation, the major details of the skull and serial sections through the principal areas of the brain. There is an excellent index. The book deserves the highest recommendation. It is finely printed on excellent paper and both the publisher and the author ought to be congratulated on producing an epoch-making contribution to the medical literature.

*Hospital Care in the United States. A study of the function of the general hospital. Its role in the care of all types of illness and the conduct of activities related to patient service with recommendations for its extension and integration for more adequate care of the American public.* 8<sup>th</sup>, cloth 631 pp., with 94 tables and 58 charts. New York The Commonwealth Fund, 1947 \$4.50

In 1932 the Committee on the Costs of Medical Care presented the first comprehensive study of sickness, health and hospitals in the United States considered the problem of sickness, treatment and prevention as well as the extent of availability and use of medical care. The report computed its cost to the patient and income to the physician. It presented the needs of the country in doctors and hospital beds separating the cost of sickness into hospital and nursing expenses, charges for medicines and professional fees. It

clearly established the importance of hospitals in the medical structure.

The report of the Commission on Hospital Care further emphasizes the strategic position of the hospital by devoting its entire 600 pages to a discussion of the function of the general hospital in the care of all types of illness. The study also discusses patient service and makes recommendations for its extension and integration for more adequate care.

The Commission consisted of twenty-two persons in addition to a study staff of nine members and eight technical advisers, assembled in 1944 by a post-war planning committee appointed by the trustees of the American Hospital Association. It was financed by The Commonwealth Fund, the W. W. Kellogg Foundation and the National Foundation for Infantile Paralysis. Although the work antedated and was separate from the surveys authorized by the Hospital Survey and Construction Act, its activities undoubtedly influenced the Congress and advanced surveys in the states. The report is presented "to the American people as a guide to the future development of hospital care and as such commends itself to all serious students of medical and hospital problems."

The one hundred and eighty-one conclusions and recommendations presented in the second chapter appear overwhelming until it is realized that this section summarizes the wide variety of subjects covered in detail in the next three hundred pages.

Section III lays a foundation of facts and information dealing with a diversity of subjects including factors that have influenced the growth of hospitals, such as religion and war, the growth of hospitals in the United States, the functions of a general hospital, its relations with public health departments and standards of service and financing.

The following sections present new and original data regarding the size and need of hospital facilities such as population vital indexes, socioeconomic conditions, geography and transportation, the relation of bed-occupancy rate to size of hospital, the effect of urban or rural surroundings, and finally a formula for measuring the need of a community for hospital facilities by means of the ratio of beds to deaths.

It has been found that the public uses two hundred and fifty days of general hospital care for each death and correlated sickness cared for in a general hospital. On an annual basis adjustment of this figure gives 0.7 bed for each hospital death (bed-death ratio). This ratio must be adjusted again to allow for a normal occupancy of 75 per cent, or 0.875 beds. The death rate in the nation is 10.6 per 1000. The Commission assumed that half these might properly be expected to occur in hospitals or 5.3. Consequently 5 beds was computed as the number of general hospital and allied special-hospital beds per 1000 population as the ultimate and ideal future need of the nation.

There are many methods of computing hospital-bed needs but the Commission recommends this as the most reliable, pointing out that it is applicable under varying conditions of urban and rural areas, in districts of both low and high incomes and in other economic or population conditions and that it expresses accurately the ratio of actual use as well as the anticipated immediate needs and can also be used to foretell future needs. For example, when hospital deaths are 4.0 per 1000 occupied beds are 2.8 per 1000 population. As hospital deaths increase so should the number of beds available be increased up to the assumed maximum of 5 beds per 1000 population.

These three hundred pages are the heart of the report and represent the constructive work of the Commission. The final two hundred pages present the best history of hospital development in the United States yet compiled and one to which reference will be gratefully made for years to come.

The final chapter presents a useful listing of all the governmental departments and agencies with which hospital administrators have to deal.

In short, this is primarily a reference book of great value for the planning of hospital development, illustrated with well explained charts and tables graphically showing the wide variation of hospital facilities and services in the different states. A practical yardstick for measuring hospital bed needs in the bed-death ratio, and future development and expansion for both urban and rural communities is intelligently discussed. Finally there is an interesting and instructive history of hospital development in the United States.

## ANNOUNCEMENTS

Dr Robert L. Cook announces the removal of his office to 38 Russell Park, Quincy

Dr Edward H. Hommel announces the removal of his office to 196 Dorchester Street, South Boston

Dr Samuel B. Kirkwood announces the removal of his office for the practice of obstetrics and gynecology to 1180 Beacon Street, Brookline

Dr Samuel Orlov announces the removal of his office for the practice of general medicine to 10 Reland Street, Middleboro

Dr Philip E. A. Sheridan announces the removal of his office to 80 Bay State Road, Boston

Drs Jacob H. Swartz and Earl A. Glicklich announce the removal of their office to 422 Beacon Street, Boston, for the practice of skin diseases

## BOSTON MEDICAL HISTORY CLUB

A meeting of the Boston Medical History Club will be held in Sprague Hall, Boston Medical Library, 8 Fenway, on Monday, January 12, at 8 15 p.m. I. Bernard Cohen, Ph.D., instructor in the history of science and general education, Harvard University, and managing editor of *Isis*, will speak on the subject "Some Scientific and Medical Aspects of Benjamin Franklin in Relation to Medicine and Science."

All interested persons are cordially invited to attend

## NEW ENGLAND HEART ASSOCIATION

A meeting of the New England Heart Association will be held at the Peter Bent Brigham Hospital, Boston, on Monday, January 26, at 8 15 p.m., with Dr. Samuel A. Levine presiding

## PROGRAM

Auscultatory Findings in Auricular Flutter Drs W. Proctor Harvey and Samuel A. Levine.  
Studies on Cardiac Tamponade Drs H. Hellems, J. M. Evans and Lewis Dexter  
Present Status of Surgical Treatment of Coarctation of the Aorta Dr Robert E. Gross  
Wolff-Parkinson-White Syndrome and Myocardial Infarction with Demonstration of Anomalous Bundle Drs Harold D. Levine and J. C. Burge, Jr.  
Physiological Studies on Eisenmenger's Complex Drs James Dow, Eugene C. Eppinger and C. Sidney Burwell  
A Neglected Form of Reversible Heart Failure Drs Edward Phillips and Samuel A. Levine

Interested physicians and medical students are cordially invited to attend

## NORFOLK DISTRICT MEDICAL SOCIETY

A meeting of the Norfolk District Medical Society will be held at the Boston Medical Library, 8 Fenway, Boston, on Tuesday, January 27, at 8 p.m. A panel discussion on bleeding from the alimentary tract will be led by Dr. Arthur W. Allen, assisted by Drs. Franklin W. White, Richard B. Cattell, Thomas H. Lanman and Robert R. Linton, followed by a period of questions from the floor. A collation will be served. All physicians are invited.

## ELLA SACHS PLOTZ FOUNDATION FOR THE ADVANCEMENT OF SCIENTIFIC INVESTIGATION

During the twenty-fourth year of the Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation,

fifty-two applications for grants were received by the Trustees, twenty-one of which came from the United States, the other thirty-one coming from thirteen different countries in Europe, Asia and North and South America. Twenty-six grants were distributed.

Applications for grants to be held during the year 1948-1949 must be in the hands of the Executive Committee before April 15, 1948. There are no formal application blanks, but letters asking for aid must state definitely the qualifications of the investigator, an accurate description of the research, the size of the grant requested and the specific use of the money to be expended. In their requests for aid applicants should state whether or not they have approached other foundations for financial assistance and what other sources of support are relied on for research. It is highly desirable to include letters of recommendation from the directors of the departments in which the work is to be done. Only applicants complying with the above conditions will be considered. Applications should be sent to Dr. Joseph C. Aub, Massachusetts General Hospital, Fruit Street, Boston 14.

## SOCIETY MEETINGS AND CONFERENCES

## CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, JANUARY 15

## FRIDAY, JANUARY 16

\*9:00-10:00 a.m. Diagnosis of Thyroid Deficiency and the Use of Thyroid Hormone Therapy in Infants, Children and Adolescents. Dr. Nathan B. Talbot. Joseph H. Pratt Diagnostic Hospital.

\*10:00 a.m.-12:00 p.m. Medical Staff Rounds. Peter Bent Brigham Hospital.

## MONDAY, JANUARY 19

\*12:15-1:15 p.m. Clinicopathological Conference. Peter Bent Brigham Hospital.

## TUESDAY, JANUARY 20

12:00 p.m. X-Ray Conference. Margaret Jewett Hall, Mt. Auburn Hospital, Cambridge.

\*12:15-1:15 p.m. Clinicorontgenological Conference. Peter Bent Brigham Hospital.

## WEDNESDAY, JANUARY 21

\*9:00-10:00 a.m. Recurrent Spontaneous Pneumothoraces and Their Surgical Treatment. Dr. Francis M. Woods. Joseph H. Pratt Diagnostic Hospital.

\*12:00 p.m. Grand Rounds and Clinicopathological Conference (Children's Hospital). Amphitheater, Peter Bent Brigham Hospital.

\*2:00-3:00 p.m. Combined Clinic by the Medical, Surgical and Orthopedic Services. Amphitheater, Children's Hospital.

## PRESENT-DAY STATUS OF POLIOMYELITIS\*

WILLIAM T. GREEN, MD†

BOSTON

**P**ERIODIC assessment of knowledge regarding infantile paralysis is highly desirable. I know of no other disease in which the public has such a great interest and, in turn, apprehension out of proportion to its incidence, morbidity, and mortality. Many sensational statements regarding new developments are reported in the lay press with very little corresponding information available in medical journals and without scientific confirmation. This makes it difficult for members of the medical profession not working in this particular field to keep informed regarding developments, real or alleged, affecting the disease. The public is much more likely to be aware of exaggerated, false claims than of actual scientific advances. Why should such sensational and unsubstantiated claims pervade the atmosphere in this disease?

The nature of poliomyelitis itself is the greatest factor. The disease is extremely variable in some cases it produces no recognizable paralysis, and in others it causes total paralysis, with all variants in between. The completeness of recovery depends to a considerable extent on the original degree of involvement, yet in the acute, preparalytic stage, it is impossible to estimate the amount of paralysis and disability that will occur. A considerable percentage of patients seen in this stage will recover completely if no specific treatment is given.

The original sampling of patients becomes a significant factor in determining the results obtained in any group of cases. If a report is based upon cases that are included in the series in the preparalytic stage, the results obtained will be statistically very good, since many of the patients will recover completely whatever the treatment they receive, whereas if the group is composed of patients who are admitted in the paralytic stage and of those who are referred when seriously involved, the apparent results will be much less favorable.

It is easy to produce a report indicating that a new treatment is excellent merely by establishing the criterion that the therapy is effective only if given in the preparalytic stage. Since many mild and nonparalytic cases will thereby be included, the recovery on a percentage basis will be excellent.

The problem of evaluating reports is further complicated by the fact that, owing to a chain of circumstances, many people have entered the field of therapy of infantile paralysis with little appreciation of the basic nature of the process and without previous experience.

In a disease of such characteristics, "new treatments" that are introduced are described as changing the prognosis radically. One of these new treatments that has been widely popularized was said to be based upon a new concept of the disease, in which paralysis was relegated to a minor role. This method was reported to be revolutionary in its results and was extensively publicized, this publicity marked the beginning of sensationalism in infantile paralysis, which still continues. Other treatments have been reported and carried to the public without scientific confirmation.

Furthermore, an organization, nationwide in scope, is concerned with raising funds to combat the disease. This keeps the subject before the public, and despite the desire of this organization to educate the public only in scientific facts, such a result is not always obtained. It should be the desire of the medical profession to keep the public informed of scientific achievements in medicine, but this educational program must involve substantiated scientific facts.

Knowledge regarding infantile paralysis is accumulating, not by revolution but by evolution. Research in this field has increased greatly in recent years, largely under the impetus given by the funds of the National Foundation for Infantile Paralysis. Important information has been added, and yet in its practical import the total contribution has been disappointing. This does not belittle the work that has been done or reflect on its necessary character.

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1947.

†Orthopedic surgeon-in-chief, Children's and Peter Bent Brigham hospitals; clinical professor of orthopedic surgery, Harvard Medical School; director, Massachusetts Infantile Paralysis Clinic, Children's Hospital.

In the field of epidemiology, for example, the usual method of spread of the disease still remains in doubt, although many factors regarding the natural history of the virus are better understood. The presence of the virus not only in the stools of patients and contacts but also in sewage and flies and the evidence of a carrier state tend toward a better understanding of the means by which the disease is communicated. The evidence is that the virus is quite widespread in times of epidemics and that relative immunity, at least to the neurotropic factors of the disease, plays a large part in the epidemiology. This may well be due to the fact that most people have had the disease in the subclinical form. Yet the usual method of transmission still remains unknown. Lack of this knowledge, incidentally, increases the apprehension of the public.

One feature of the epidemiology should be emphasized—the increased incidence of bulbar poliomyelitis in patients shortly after tonsillectomy. Since this is the form of the disease with the highest mortality, tonsillectomy performed during a poliomyelitis epidemic or when endemic cases are occurring is, under ordinary circumstances, undesirable.

It is impossible in a short time to discuss in any detail the recent contributions of research. Electromyography has been of assistance in interpreting the abnormal neuromuscular physiology in the disease. The neurotropic character of the virus and the diffuseness of the involvement of the nervous system have been confirmed and emphasized. However, we are still without a method of increasing either passive or active immunity to the virus. The real advance will come when infantile paralysis can be prevented, but for the present we are confronted with the necessity of treating the disease as effectively as we can to obtain the maximal functional result.

Before therapy is considered, certain clinical features of poliomyelitis should briefly be reviewed, and the pathologic process, so far as it is essential for this discussion, should be considered.

#### CLINICAL AND PATHOLOGIC CONSIDERATIONS

Infantile paralysis is characterized by an acute illness that, in its first phase, may be nonspecific but soon causes symptoms referable to the central nervous system, with increasing sensitivity, spasm and paralysis. Not infrequently, between the early nonspecific portion of the acute illness and the period when symptoms referable to the central nervous system occur, an afebrile stage of from one to five or even seven days may exist, giving a diphasic character to the acute illness. The acute febrile stage of the disease may be very short, but usually lasts from five to ten days, after which an increase in the degree of paralysis is rare. Death, if it occurs, is ordinarily due either to respiratory involvement or to bulbar paralysis.

Paralysis of recognizable degree may or may not be present, and the distribution is extremely variable. It may affect but few muscles, it may affect all. It tends to be regional in its distribution, although a patchy character is common. The effect on individual muscles varies from slight weakness to complete paralysis.

The particular combination of neuromuscular effects that the disease produces causes it to be deforming and disabling. The paralysis is the factor of chief importance, but in the early stage, the spasm contributes to the deformity and in turn to the disability. If one pictures a disease in which one group of muscles may be paralyzed, and the opposite group controlling the part are in painful spasm and shortened, it can be appreciated that deformity will result. This tendency is increased by the fact that carrying the part out of deformity is painful. To add to the difficulty, if parts are left for a period in a deformed position, a secondary myostatic contraction develops, and the deformed position becomes fixed. Furthermore, deformity, as well as sensitivity and muscle spasm, inhibits muscle function and, in turn, the return of muscle power.

Although the effect of the disease on the central nervous system is quite widespread, the main destructive action is on the anterior-horn cells, producing a flaccid paralysis. It should be emphasized that the action on the anterior-horn cells supplying a particular muscle may vary in all degrees up to their total destruction, and hence from temporary neuronal injury with rapid recovery of function to irrevocable paralysis. It must likewise be considered that weakness of a muscle, short of complete paralysis, is due to the involvement of a particular proportion of its neuromuscular units and that even in muscles severely involved one or more residual neuromuscular units usually remain. These, for purposes of therapy, are designated as "guiding contractile units."

If the involvement is severe, the recovery of the power of the muscles extends over a considerable period, but it usually may be said to be completed in sixteen months, with the greatest degree of recovery in the earlier part of this period. In the individual muscle, the prognosis for recovery cannot be anticipated in the early paralytic stage. The greater the degree of paralysis at the start, the less likely is complete recovery of the particular muscle, especially if the paralysis is equally extensive in the regional area.

The pathologic mechanism that produces the sensitivity and spasm remains unknown. Lovett years ago suggested that the involvement of the posterior ganglions might be the factor. The possibility that it is due to effects on the internuncial neurons or on neurons with an inhibiting or stimulating action on the anterior-horn cells has been proposed. It should be emphasized that the spasm

is not the most damaging effect of the disease, as proposed in the Kenny concept, but that it is a symptom that, with sensitivity, tends to be deforming in the early stages. Pain and muscle spasm inhibit muscle function during the acute stage, but the disability of consequence arises from the paralysis. Spasm becomes important in the end result only when paralysis exists.

### TREATMENT

Progress in the therapy of poliomyelitis has been one of gradual evolution based on physiologic principles as applied to the pathologic process. The flurry accompanying the Kenny method has receded. It has stimulated a re-evaluation of technics, and, in fact, in this way it has been most beneficial. Curare and prostigmine have not been demonstrated to be of particular value. Their use is based upon an idea that the spasm is of greater significance than present knowledge can substantiate.

Treatment depends upon the stages of the disease and the degree of involvement. It is best considered by subdividing the disease into three stages—a modification of Lovett's original classification. The first is the acute stage, which may be described as the period of the acute febrile illness, and which may, in turn, be subdivided into a preparalytic and a paralytic phase. The second is the convalescent stage or stage of recovery—the period during which muscles may recover their power—and may be said to end in sixteen months, this may be subdivided into the sensitive phase and the insensitive phase, the first, or sensitive phase, ending when the sensitivity and muscle spasm are no longer present. The third stage (the chronic or residual stage), which follows the convalescent stage, is the period after actual recovery of the muscles is to be expected, although the functional capacities of the patient may be greatly improved during this phase.

#### *Acute Stage*

In the acute stage, the treatment is mainly symptomatic. Bed rest is essential, and the patient's activities should be minimal under these conditions. He should not be allowed to wait upon himself. To carry the idea farther if, in epidemic periods, a patient has a minor illness of nonspecific character that might possibly be the first stage of the diphasic type of onset, his activities should be curtailed for a sufficient period after the temperature has returned to normal to establish the fact that the disease is not present. There is evidence, for example, that fatigue and overactivity during this period, such as swimming in cold water, increase the morbidity of the disease.

With the onset of symptoms referable to the central nervous system, such as sensitivity and spasm, heat in the form of intermittent hot packs may be applied to the sensitive areas as indicated, although prolonged hot packs, which are debilitating,

are contraindicated. When paralysis occurs, careful attention to the position of the parts, which must be supported and kept out of persistent harmful attitudes, should be given. Fixed positions for any considerable period should be avoided. Gentle handling of the patient is imperative, and sedation should be used as indicated. Sedatives should not be employed, however, as a substitute for good care.

During the stage of developing paralysis, the patient should be observed frequently for evidence of respiratory involvement or bulbar paralysis. If there are any signs of either type of involvement, constant nursing attention is essential, and the physician must be prepared to meet the emergency.

Bulbar involvement is indicated by such signs as difficulty in swallowing, changes in the voice and irregularity of respiration. Spinal respiratory paralysis is suggested by diminishing respiratory excursion, asymmetric or other abnormal yet rhythmic motions of the chest, use of the accessory muscles of respiration, shortness of breath and cyanosis.

These two types of involvement must be carefully differentiated, since the method of treatment of one is entirely different from that of the other, and to confuse them may result in a fatal outcome. In the bulbar type, the immediate indications are to keep the head dependent to allow for drainage, suction of the pharynx, parenteral feeding and manual aid to respiration if there are transient periods of difficulty. In the spinal respiratory type, the use of a respirator is indicated and may be lifesaving. Only rarely is a respirator indicated in the bulbar type of paralysis, as when the center actually fails completely or when the bulbar form is combined with the spinal respiratory type. Tracheotomy may occasionally be necessary but only on specific indication.

In patients with a fixed elevated chest, continuous local hot packs may be helpful. Feeding by gavage is contraindicated in the bulbar type of the disease if the patient cannot swallow, since vomiting may occur, with disastrous results. Continuous special care is essential in bulbar poliomyelitis since this type has a high rate of mortality that can thereby be greatly reduced. The problem in this type is emphasized by the knowledge that if a patient with bulbar poliomyelitis survives the acute stage, he usually recovers completely. I am particularly pleased to report that the death rate in infantile paralysis at the Children's Hospital, Boston, during the last three years has been slightly under 2 per cent.

#### *Convalescent Stage*

The return of the patient's temperature to normal marks no abrupt transition in treatment, but the therapy directed toward the neuromuscular abnormalities becomes more active. In the first phase of this stage, the patient is usually quite sensitive. All handling must be gentle, and motions of the involved parts should be assisted.

Hot packs are continued as indicated to alleviate the spasm, which of itself is deforming. Packs of the lay-on type are most frequently used. These may be applied several times a day and ordinarily are employed only on particular areas where the spasm is deforming and uncomfortable. It is well to add that hot packs have been used at the Children's Hospital during the sensitive stage of the disease for over twenty-five years.

In this stage, more effort is directed toward maintaining the desired anatomic position. Exercises involving gentle passive motions are performed several times daily to carry the position out of deformity and to develop an increasing range of motion. Correction at this stage should not be forced or painful. Parts are maintained in as good a position as possible and supported as necessary. Support to the feet in particular, whether with a portable foot support or a bedboard, is needed. The bedboard with the mattress pulled away from the foot of the bed (Kenny) allows the foot to be maintained at a right angle when the patient is prone. If it is difficult to control a deformity, bivalved plaster splints or wire splints are often indicated, particularly to support the feet. The splints are frequently used only part of the day and at night. This does not in any way deviate from the principle that parts should not be left in one position for long periods and in no way interferes with other factors of treatment.

An estimate of muscle function recording the degree of involvement should be made after the temperature has been normal for forty-eight hours, or shortly thereafter. This should be followed by an accurate "muscle examination" recording the functional power of the various muscles as soon as it can be accomplished painlessly and without disturbing the patient. This often needs to be done in piecemeal fashion. Such an examination is performed at regular intervals to record the progress of recovery. Active exercises are based on this examination.

Active guided exercises are added early on a graduated scale, discomfort and fatigue being avoided. These active exercises follow the principle that the weak muscles are required to carry out their function without allowing other muscles to substitute for their action. If a muscle cannot perform the action, the action is performed with a therapist assisting in the motion but with the patient making every effort to use the muscle. The position of the exercise varies according to the strength of the muscle and the function that can be elicited in the particular position.

These active exercises are based both on empiric observations and on physiologic principles. It is recalled that anterior-horn cells may be involved to any degree and that their function may be lost for a considerable period without death of the neuron and with consequent recovery of function.

Furthermore, if a muscle is left out of a particular pattern of motion for a period, it may recover its potentiality of function without returning to the pattern. During the convalescent stage when recovery is possible, it is quite important to maintain by exercises the action of the paralyzed muscle. If the weak muscle is not protected and stimulated to contract, and instead indiscriminate substitute motions are performed at all times, the weak muscle may drop out of the pattern completely. In this connection, it is well to remember that guiding contractile neuromuscular units exist for most muscles, even those severely affected. If all anterior-horn cells have been destroyed for a particular muscle, active exercises for this muscle are of no consequence. This, however, cannot be foretold during the earlier part, at least, of the convalescent stage.

Underwater therapy is highly valuable in the sensitive stage as well as in the later period of convalescence. The Hubbard tub is used early with the water at as high a temperature as is tolerated comfortably by the patient. This decreases the spasm and sensitivity and aids, with exercises in the water, in developing a range of motion and in correcting deformities. As the sensitivity decreases, exercises in a tub with water at a lower temperature and, in turn, in a pool, are of great assistance, particularly in patients who have considerable involvement.

*Insensitive phase.* After the insensitive phase of the convalescent stage is reached, actual stretching of the contracted parts is often necessary, and the active exercises are increased as tolerated. The first problem is to get the patient to use the afflicted muscle properly. Later, exercises are added that increase strength and produce hypertrophy. Part-time support for parts with deforming tendencies is often still needed.

Sitting and standing are ordinarily instituted in this stage also. This transition must be carefully supervised, and one must make sure that these activities are performed with as good a balance as possible without deformity being increased, and determine that the various muscles are used in as normal a functional pattern as possible. Crutches are often a desirable aid in walking at the start, depending upon the involvement of the arms. Walking braces are not ordinarily used during the convalescent stage until the maximal recovery of muscles has occurred, provided that the patient, when ready to walk, is able to walk without inducing further deformities. Walking of itself is an essential exercise if properly performed. Walking braces may be used during the latter part of the convalescent stage when it becomes apparent that they are necessary for effective locomotion. In the chronic stage, a brace should be used at least part time if the patient can walk more effectively with it than without it.

### *Chronic Stage*

In the chronic stage, the problem is to make the patient as effective as possible, despite the residual involvement. Particular cases may need regular stretching of certain parts. Muscles of borderline strength may need exercises designed to produce hypertrophy. Occasionally, support of one kind or another is needed for use at night.

Functional and gait training are most helpful in this period, particularly in patients who have had severe involvement or who have not been well supervised in their early course. Whereas, in the convalescent stage, muscle substitution is prevented, in this stage, if it is necessary, it is cultivated and supervised to produce the best function despite the paralysis. The adult may require little supervision in the chronic stage unless he has very extensive involvement, whereas the child with residual involvement should be supervised regularly during the growing period, since deformities may progress, owing to disturbances in growth.

It is also in the chronic stage that operative intervention may be indicated in such forms as tendon transplantation to supply a needed muscle function, fusion of parts by arthrodesis or corrections of deformities and improvement of function by other surgical means. Considerable progress has been made in the operative rehabilitation of patients in recent years.

\* \* \*

The treatment of infantile paralysis may be very simple in patients with mild involvement, and the outline of therapy presented above is interrupted as indicated. In a small percentage of cases it is a long, arduous task requiring highly skilled, patient, physical therapists and careful medical supervision by those experienced in the disease.

Ideally, it is believed that the patient with acute poliomyelitis should be supervised from the start by a team composed of a pediatrician or internist and an orthopedic surgeon, or at least someone experienced in the care of the musculoskeletal system in this disease. Attention must be given to the care of the musculoskeletal system from the start, thus preventing deformities and complications and simplifying the later treatment.

All patients, from the onset of the disease, are best cared for in a hospital. This would not necessarily be true if it were not for the possibility of a bulbar or respiratory paralysis. However, transportation of patients for long distances during the acute febrile stage should ordinarily be avoided.

Since an epidemic may occur at any time, one must be prepared to care for patients in the acute stage in local hospitals. After the febrile stage, if there is much involvement, treatment may be necessary in a special unit with an adequate staff of experienced physiotherapists, under proper supervision. It is well to recall that death, if it occurs, is most likely to happen during the acute stage, and the hospital caring for the acute disease must be prepared to give the best of supervision in this stage. In a large percentage of children the treatment after the sensitive period of the convalescent stage can be carried out at home if the mother is carefully instructed regarding the exercises and routine of care, and provided the child is supervised at regular intervals by the physician and physical therapist. The expense of care can thus be greatly decreased.

Knowledge of infantile paralysis is increasing, and therapy in the disease is improving, but not by any revolutionary discoveries.

## THE TREATMENT OF POLYCYTHEMIA VERA BY SPRAY IRRADIATION\*

WYMAN RICHARDSON, M D,† AND LAURENCE L ROBBINS, M D ‡

BOSTON

IN 1932 the treatment of polycythemia vera by spray irradiation was instituted at the Massachusetts General Hospital by the Department of Radiology at the suggestion of Dr Francis T Hunter. The results of treatment at the end of a ten-year period were presented by Robbins.<sup>1</sup> The purpose of this study is to report upon the present status of the original group of patients and also upon the results of treatment in 8 additional patients. This method of treating polycythemia vera has proved the most successful of any of the procedures that have been tried at this hospital, and it has seemed worth while, for the benefit of the clinician, to re-emphasize its value.

Irradiation of the bone marrow in cases of polycythemia vera was first suggested in 1907 by Stengel.<sup>2</sup> Lüdin,<sup>3</sup> in 1916, was the first to treat the disease successfully by irradiating the long bones of the skeleton. In 1932 Sgalitzer<sup>4</sup> reported good results from irradiation of the entire body. Similar reports followed from Hunter<sup>5</sup> and Sanderson<sup>6</sup> in 1936 and from Pierson and Smith<sup>7</sup> in 1940.

The investigations of Lawrence and his associates<sup>8, 9</sup> and others<sup>10, 11</sup> on the use of irradiated phosphorus suggest that in the future this may be the treatment of choice in polycythemia. The advantages of its administration are threefold: it causes less discomfort to the patient, its administration is easy, and it takes less time than irradiation by x-ray. On the other hand, a universal standard for measurement of radioactivity is lacking, and its long-range effects are still unknown. Radioactive isotopes, even though the "half-life" may seem safe, introduce a form of radioactivity whose long-term effects cannot yet be predicted. The same criticism may be applied to spray irradiation and may account for the reluctance of some physicians to make use of it. The experience at this hospital has been limited purposely to the use of the latter form of treatment because of its apparent success, and to keep this series of cases intact. The time may come, however, when radioactive isotopes will prove to be of greater value.

It is the policy of the hospital not to use any form of prolonged irradiation, whether for diagnosis, treatment or study, in persons who are not sick or who have a self-limited or benign disease. Polycythemia, however, whether neoplastic or not, in-

variably ends fatally and must be considered and treated as a malignant disease.

### METHOD OF TREATMENT

Spray irradiation is given with the intention of covering a field extending from the neck to the knees of the average person. This requires a long target-skin distance, which varies from 215 to 250 cm., and can usually be accomplished with a 20-by-20 cone on the machine. The area is centered at the level of the crest of the ilium, and anterior and posterior fields are treated on alternate days.

The following factors have been found satisfactory: kilovoltage of 200, 0.5 mm of copper and 1.0 mm of aluminum filtration, which gives a half-value layer of 0.92 mm of copper. The daily dose varies from 20 to 30 r, measured in air, and the total dose is approximately 300 to 500 r in any one series of treatments, divided between an anterior and a posterior field. The small daily dose usually prevents severe roentgen-ray sickness, and the repeated small assaults on the bone marrow may have a more prolonged effect than larger daily doses. Some of the first patients treated received larger daily doses and larger total doses, but the method outlined above has seemed to be safe and satisfactory. It produces fairly prolonged remissions without causing incapacitating radiation sickness, and with these doses there has been, with one possible exception, no definite injury to any of the patients.

The amount of treatment is determined by the total white-cell count. Such a count is taken at the beginning of treatment, at the end of a week, and at shorter intervals as the cells decrease, toward the end of treatment daily counts are taken. When the count falls below 5000 to 6000, treatment is stopped. No particular attention is paid during treatment to the red-cell count or to the hemoglobin level, since these determinations usually do not change significantly until a month or two after the treatment has been completed.

Tables 1 and 2 give the over-all results in 28 cases of polycythemia vera. To summarize the available data in a not too cumbersome form, certain laboratory findings, such as hematocrit determinations and oxygen-capacity studies, have been omitted. In the opinion of some investigators hematocrit determinations are considered indispensable in the treatment of patients with polycythemia vera. Experience in this hospital has shown, however, that the total clinical picture, together with white-cell and red-cell counts and perhaps photoelectric hemo-

globin determinations, are sufficient and require considerably less time.

Twelve patients died, as compared to 16 who are alive. These results do not seem impressive until the causes of death are analyzed, many of the deaths were due to conditions other than polycythemia. Furthermore, this disease typically occurs in elderly persons, in whom life expectancy is short. In none of the group did leukemia, a leukemoid state or so-called "myeloid metaplasia" develop.

Table 3 presents details regarding the fatal cases. Two patients died of pulmonary disease apparently not related to polycythemia, 1 died of carcinoma of the breast two years after its discovery and eight years after irradiation for polycythemia had been started, and 1 died of uremia due to prostatic obstruction. It is not believed that these deaths were due either to the polycythemia or to its treatment.

Six deaths were caused by arterial thromboses (3 coronary, 2 cerebral and 1 cerebral, aortic and

It is difficult to assess the effect of polycythemia vera in producing vascular disease. Obviously, relatively few patients in this age group who develop

20	4.65	8,600	13.0	78	Patient died in nursing home $1\frac{1}{2}$ years after first treatment, cause of death unknown — probably polycythemia.

\*Patient died outside hospital, no autopsy performed.

†Sahli.

In this case benzene (benzol) may have been a causative factor of the disease, but in spite of this fact and the possibility that irradiation was responsible for the present anemia, irradiation would have been

basis from which to draw conclusions. In general, it appears that the larger the total x-ray dosage, the longer the remission. The size of the dose, however, is limited by an increasing tendency to leukopenia

TABLE 4 *Status of 16 Living Patients (as of December, 1946)*

27	5.06	8,400	17.5	1.5	Lack of left hand co-ordination on admission; now well.
28	4.22	5,900	17.8	3.5	Headaches and nosebleeds on admission; now well.

considered the treatment of choice. One patient, although still alive after seven years, has numerous symptoms and an increased red-cell count, and this case is considered a therapeutic failure.

The table suggests that a total dosage of between 400 and 500 r will produce good results.

The total white-cell count has proved the best criterion for determining the amount of irradiation

to be given. When the total count falls below 5000 treatment is discontinued. A count of 1800 or less has resulted from some of the larger doses, but there have been no symptoms and no fatalities from this cause. Especially during the early years of this type of treatment, some patients who received a relatively large dose experienced unusually long remissions of symptoms.

### DISCUSSION

The treatment of polycythemia vera by blood-letting is physiologically unsound for several reasons. Blood loss is known to be one of the greatest stimuli to bone-marrow activity and blood-cell production. Such a procedure relieves only one of the complicating factors—namely, increased blood volume; it does not affect platelet production, except by increasing it, and may have no effect in preventing vascular thrombosis. Most patients treated by this method are never quite well even when frequently

Phlebotomy may be indicated, however, for the immediate relief of acute symptoms or when disaster threatens.

Difficulties in the use of phenylhydrazine are well known and require little comment. One of the greatest is in regulating the dosage, since not only do different persons react very differently to the drug but also a single patient may react unpredictably to a constant dosage. Its advantage (or disadvantage?) over phlebotomy lies in the fact that materials necessary for the synthesis of hemoglobin are conserved, and "hypochromic polycythemia" does not develop so readily. The use of this drug has largely been given up.

Theoretically, the use of spray irradiation seems to be a sound approach to the problem since it aims to inhibit an overproductive bone marrow. The results in this series of patients tend to confirm this theory, many of the patients having normal blood pictures for long periods after treatment. A great

bled, they need so much medical attention that they consider themselves, and are considered to be, chronic invalids. Phlebotomy eventually results in a condition of plethoric anemia, or hypochromic polycythemia, which is incompatible with good health. Finally, many of these patients develop a condition, variously described as "lenkemia," "lenkemoid state" or "myeloid metaplasia," which ends fatally.

An example of this is the case of a private patient, not included in this series, who was referred for treatment, after repeated phlebotomies, because of gangrene of the fingers. The blood picture was that of extensive extramedullary hematopoiesis ("myeloid metaplasia") with a severe hypochromic polycythemia, a white-cell picture suggesting myelogenous leukemia and vastly increased platelets. The fingers healed after one course of spray irradiation, the blood picture returned to normal after two courses, but a fatal anemia developed after a third course, two years later, made necessary by a recurrence of impending gangrene in the fingers and by a greatly increased number of platelets. The patient refused to re-enter the hospital for transfusions and further study, and died at home.

advantage of this type of irradiation is that patients so treated are perfectly well, often for years, requiring little medical attention, except for an occasional checkup of the blood picture. Another advantage is the fact that it does not produce a plethoric hypochromia and does not end in "leukemia" or "myeloid metaplasia." Vascular thromboses appear to be checked, and life may be prolonged, perhaps for a considerable time. The data in this study, however, are obviously insufficient to justify any positive statement. (The deaths of 6 patients from vascular disease are discussed above.)

The disadvantages of spray irradiation, pointed out above, are the suffering caused by roentgen sickness, the time and effort consumed in completing a course of treatment, the possibility of producing a refractory anemia (one of the 28 patients treated has such an anemia, possibly or probably due to treatment), and the possibility of deleterious, long-range effects. Except for the patient with anemia and the possibility (rather farfetched) that carcinoma of the breast developed in another case as a result of roentgen irradiation, none of the group developed any such condition.

A statistical presentation of the results does not give a clear picture of the actual value of this form of treatment. The following of individual patients over a number of years, however, is very impressive, the results in a small group of private patients, not included in this report, are even more impressive. The following case is an example.

A 61-year-old woman with polycythemia was first seen in 1936. At that time she had numerous complaints, especially a severe type of peripheral neuritic pain. The red-cell count was in the vicinity of 11,000,000. In the past 11 years she has received four courses of spray irradiation, totaling 2100 r, and has remained entirely well. She is now 72 years old.\*

Although this is but a single case, no comparable result has been found in the reports of those advocating phlebotomy.

Further evidence of the value of spray irradiation therapy derives from the fact that it is resorted to when bloodletting has nearly resulted in death. Three such private patients have been seen at this hospital, 1 of whom died of anemia two years after spray treatment had been begun but who enjoyed better health during that period than he had for many years previously. A second patient, who had a very abnormal "leukemoid" blood picture with hypochromic polycythemia following many years of repeated phlebotomies, is at present well (two years after treatment), with a normal blood picture. The third patient is just completing his first course of treatment. It is not satisfactory to irradiate such patients with abnormal blood pictures due to long-continued bloodletting, they should rather be treated from the beginning by spray irradiation.

Another private patient not included in the group was discovered to have polycythemia vera as a cause for extensive venous, and probably, peripheral-artery thromboses. Bloodletting became impossible because of venous thromboses at the site of the venepuncture. The man was told that nothing more could be done for him. At that time, two years ago, a single course of spray irradiation was given. There has been no subsequent recurrence of thrombosis, and there has been a considerable improvement in the venous circulation.

It should be emphasized that spray irradiation may be a particularly dangerous form of therapy if employed injudiciously. Its use in patients whose increase in red-cell count and in hemoglobin is due to anoxia might prove fatal. Polycythemia vera, as the name implies, is a disease associated with a considerable increase in all the cells of the blood. This

\*Since this paper was submitted for publication, this patient has died of a condition clinically and pathologically indistinguishable from acute myelogenous leukemia.

is not true of secondary polycythemia or "erythrocytosis." Spray irradiation should never be used in cases of extramedullary hematopoiesis ("myeloid metaplasia") in which the marrow itself has been replaced by tumor or other tissue, for the results may well be fatal. Finally, the not too uncommon, benign condition of familial hypochromic polycythemia, largely confined to members of the Italian race, should never be treated by irradiation. In fact, these patients need no treatment of any kind.

For the reasons stated above, radioactive isotopes have not been used in the treatment of polycythemia in this hospital, and for the moment judgment on this type of therapy is reserved.

## SUMMARY

Twenty-eight cases of polycythemia vera treated by spray irradiation are reported.

Twelve patients are dead, 4 died of causes other than the polycythemia or its treatment.

Of the 16 living patients, 13 are free of symptoms attributable to polycythemia, 1 has hypertension, 1 is anemic, and 1 is still polycythemic and is considered a therapeutic failure.

One patient has a refractory anemia, possibly or probably attributable to roentgen-ray treatment.

No patient has developed leukemia, a "leukemoid state" or "myeloid metaplasia."

Phlebotomy is contraindicated in polycythemia vera except in the treatment of acute symptoms or impending disaster.

Spray irradiation is the treatment of choice.

The use of radioactive isotopes is discussed only briefly.

## OVARIAN CONSERVATION DURING SURGERY

## With Reference to Bilateral Dermoids and Endometriosis

ALEXANDER A. LEVI, M.D.\*

BOSTON

CONSERVATION of portions of the ovary during surgery is not a difficult procedure, and yet it is not practiced commonly by general surgeons. Gynecologists are well acquainted with the fact that a very small amount of ovarian tissue will protect the patient's future well-being. Surgeons of lesser training and experience in this specialty are more likely to remove ovaries, probably because of a lack of knowledge of pathology. With increased information on this score, surgeons will remove fewer ovaries in toto and will make every effort to save as much ovarian tissue as possible.

This paper, therefore, is written to call attention to the benefits to be derived from resection, to supplement an article presented in 1939<sup>1</sup> and to make a plea for greater conservatism on the part of the surgeons dealing with ovarian surgery.

In the paper referred to, the case of a thirty-three-year-old patient was discussed.<sup>†</sup> The ovaries in this case were nearly the size of large oranges because of bilateral dermoid cysts. At operation, the right ovary was completely removed. The left was resected, a piece 1.5 cm. in diameter and as thin as a dime remained.

The pathological report, by Dr. M. F. Vidoli, was as follows:

The first specimen consisted of an ovarian cyst measuring 2.8 by 2 by 1.5 cm., and separately received with the same specimen a small, irregular, tooth-shaped section measuring 8 by 6 by 4 mm. Multiple sections showed the entire ovary to be replaced by a cystic cavity filled with greasy yellowish material and two small cysts, each measuring 6 mm. in diameter, filled with clear fluid.

The second specimen included an oval, smooth, yellowish-gray mass of doughy consistence, measuring 8 by 6 by 5 cm. Multiple sections demonstrated a large cystic cavity filled with yellow greasy material and a moderate amount of hair. Along one side, the wall became thicker, showing remnants of ovarian tissue and several smaller cysts filled with whitish gelatinous material.

The microscopical diagnosis was bilateral dermoid cysts of the ovaries.

Since the operation, which was performed on July 26, 1938, the periods have occurred regularly without undue event. Frequent pelvic examinations have disclosed no change in the residual ovarian tissue. This finding is entirely consistent with the opinion expressed by various pathologists that normal-appearing tissue is normal ovarian tissue, microscopically, in every respect. What is the rationale for removing both ovaries in such cases? Why

cause a complete menopause in a young woman? Why deprive a young woman of the possibilities of having children?

With these thoughts in mind, when a second patient with bilateral ovarian dermoid cysts presented herself, she was also treated conservatively. The subsequent history in this case<sup>‡</sup> provides such a direct answer to the questions asked above that the pertinent facts are related as follows:

During December 1936, F. W., a 28-year-old woman, reported for a premarital examination. She suspected no physical abnormalities since she had been in good health and since the menses occurred every 28 days and were of 3 days' duration. When informed of the presence of bilateral ovarian dermoid cysts and the possible consequences of the operation, she postponed her marriage and was operated upon on January 23, 1939.

The findings were strikingly similar to those in the case presented above. The right ovary was nearly the size of a large orange and was completely removed along with the tube that was attached to it. The left ovary was likewise enlarged. A small piece of normal-appearing ovary was located near the ovarian vessels. It was 'shaved off' and examined for bleeding. Since a slight ooze only occurred this piece was not further disturbed. As in the previous case it was hardly as large as a dime.

The pathological report by Dr. H. E. MacMahon was as follows:

One specimen consisting of an encapsulated structure, roughly round, measuring 7 by 5.5 by 5.5 cm. is pale yellowish pink. Along one side is a scarred projecting nodule, suggesting ovarian tissue. Section through this reveals a small follicular cyst (regressing corpus luteum). Section through the large mass shows a cavity filled with cornified epithelium. This can be peeled with some difficulty from the wall leaving a smooth glistening surface. At one point there is a small bony, hard spicule. In another, there is a small cyst filled with gelatinous mucus-like material. The gross diagnosis is epidermoid cyst.

The second specimen includes a similar cyst, which is roughly round, rather soft and buttery. There is one small, bare area. The wall measures 0.1 to 0.2 cm. in thickness. The cyst is filled with buttery, white material that can be easily removed leaving a clean surface with the exception of one point where there is a projecting nodule from which a large tuft of black hair protrudes.

The microscopical diagnosis of the first specimen is epidermoid cyst of the ovary with a small follicular cyst and that of the second, dermoid cyst showing skin and skin appendages, cartilage, smooth muscle and abundance of myelinated and nonmyelinated nerve fibers; ganglion cells of the sympathetic system. There is no evidence of malignant changes.

Two weeks after the operation, a regular period occurred. After this reassuring episode, the patient completed her plans for marriage. Nine months after the operation she skipped two periods and then flowed profusely. There was some question whether she had had a miscarriage. Subsequently she was delivered of healthy well-formed babies on October 24, 1940, December 22, 1944 and October 13, 1946.

\*Instructor in obstetrics and assistant in gynecology, Tufts College Medical School; member surgical staff, Mt. Auburn Hospital; senior visiting obstetrician, Evangeline Booth Maternity Hospital.

†Cambridge Hospital Case 5-38-518 (July 6, 1938).

‡Cambridge Hospital Case 5-39-57 (January 23, 1939).

These cases demonstrate that adherence to the advice in the older textbooks "to remove both ovaries in cases of bilateral dermoid cysts" not only is unwise but also may be calamitous

As a matter of fact, papers have appeared only recently, urging conservative ovarian surgery in such cases. An extensive search of the literature disclosed few such articles. Usually, reference to the use of conservatism is hardly more than perfunctory. So little is said that unless one is particularly interested, it is taken for granted that radical surgery is the technic to be employed in all cases of bilateral ovarian dermoid cysts.

Geist<sup>2</sup> presents photographs of a dermoid cyst resected from an ovary. Study of this illustration is interesting because it discloses a very wide resection. It seems that in his case much more normal tissue was found and retained than in either of the 2 cases described above. This photograph again emphasizes the fact that one must have the will to preserve normal tissue.

Martzloff<sup>3</sup> describes a case of a thirty-nine-year-old woman from whom, at operation, he removed the left tube and ovary, resecting the right ovary. In describing this case, he states that the right ovary was about twice the normal size. It contained a yellowish cyst, through the wall of which some hair could be seen. This cyst was resected, what would correspond to about a third of a normal ovary being left in situ. The pathological report stated that section revealed a cystic structure filled with sebaceous material in which there was some hair. The author finally commented that when last heard of the patient "had been menstruating normally at twenty-six-day intervals."

This case affords a good illustration of the possibility of conserving the ovarian function when some normal tissue is present, the danger and inconvenience of a premature operative menopause being thereby avoided.

It is interesting to note how casually Martzloff comments on avoidance of a premature operative menopause. I believe that his statement bears greater emphasis because this patient was already near the menopause (age thirty-nine) and yet the author thought in terms of preventing such an occurrence earlier than it would have taken place naturally. This is the type of reasoning that more surgeons should follow. I can say, regretfully, that I have heard many surgeons remark at operation that the patient was near the menopause, anyway, and that the ovaries would be removed "to prevent trouble later on." Such loose thinking, in my opinion, is as illogical as extirpating an eyeball from the surface of which a cinder has been removed "to prevent trouble later on."

Martzloff concludes "Out of a total of some 200 patients who have had dermoid cysts in one or both ovaries (confirmed by examination of micro-sections) we have had only one other case (two altogether),

of carcinoma developing in an ovarian dermoid cyst" (His reference is to cases at the Johns Hopkins Hospital.) This remark can well be appreciated for the important reason that it disproves so effectively what is written in textbooks as dogma that most ovarian dermoid cysts become malignant, which they obviously do not.

Furthermore, Marshall,<sup>4</sup> in a brief report, presented evidence on 415 cases of dermoid cyst, examined at the Mayo Clinic. Among other facts, he disclosed that in this series 19 per cent were malignant. Bell<sup>5</sup> believes that few surgeons give any consideration to the surgical treatment of innocent neoplasms other than the complete removal of the organ and states that, as a rule, some healthy portion of ovary can be preserved with its normal connections, for nearly every neoplasm tends to grow away from the hilus and the preservation of this, with adjacent ovarian tissue, leaves well nourished and functional tissue. Mathews<sup>6</sup> also emphasizes the wisdom of conserving ovarian tissue and points out that the line of cleavage between the cyst and ovarian tissue can easily be followed. Miller,<sup>7</sup> in a general discussion of 90 cases of ovarian dermoid cyst, concludes that conservation of ovarian tissue by enucleation of the dermoid cyst is an easy and valuable procedure.

If the advice given in the statements presented above is followed, it will quickly be discovered that this type of surgery is not too difficult. It is important, however, to operate with great care, so as not to disturb the blood supply of the tissues to be retained. It must be kept in mind that no matter how small the piece of remaining ovarian tissue is, it is well worth conserving.

The following authors are quoted because their papers likewise express the belief that it is not difficult to remove the cystic portions.

Dockerty,<sup>8</sup> of the Mayo Clinic, reviewing four hundred articles in the literature on the subject of ovarian neoplasms in general, states "When such small dermoids are encountered they should be shelled out without rupture and the resulting raw surface apposed with a minimum of fine suture material. Pregnancy has occasionally ensued after such conservation of the ovarian tissue."

I believe that it is possible to extend these remarks by the statement that conservative surgery can also be practiced in cases with large dermoid cysts. The cysts in the cases described above were each nearly the size of an orange.

Meigs<sup>9</sup> writes that dermoid cysts may be treated by excision with the ovary or excision from the ovary. He also concludes his discussion of ovarian tumors by saying "The treatment of certain ovarian lesions is definite and may be conservative. . . ."

The following cases are included in this paper because they likewise help prove the value of conservative ovarian surgery. These were cases of endometriosis, reasonably well developed, in patients

who before operation had been considered incapable of bearing children

J P \* a 22 year-old woman who had been married 13½ years, had been well up to 6 months prior to operation. During that time increasingly more painful menstrual periods had developed. On August 30, 1944, she was operated upon by me at the Cambridge Hospital. Owing to a chocolate cyst, the left ovary was nearly the size of a peach. The tube was intimately adherent to it. The uterus was in retroversion. The right tube appeared normal. The right ovary contained simple cysts. There were numerous endometrial implants over the surface of the bladder. A left salpingo-oophorectomy, incision of the cysts of the right ovary excision of the endometriomas and uterine suspension were performed.

Pathological examination by Dr MacMahon disclosed an endometrial cyst of the ovary with endometriosis of the tube and of the adjacent serosal surface. The ectopic endometrial tissue was "in secretory phase" as was the endometrium.

In November, 1945, the patient's husband returned from military service. She became pregnant during January 1946, and was delivered (because of disproportion) by low cervical cesarean section on November 2, 1946, of a healthy female baby weighing 7 pounds, 13 ounces. At this operation, the remaining right ovary was examined. It was normal in appearance.

This case also demonstrates the value of conservative ovarian surgery. It may seem that this point is being labored. If reiteration drives home a thought, it is well for the occasional operator, especially, to appreciate the value of conservatism. My belief is that this advice cannot be repeated too often and that the lives of many women, as well as their marital relations, can be saved from being wrecked by exceedingly small pieces of ovarian tissue. Greater caution must be exercised by the surgeon in his decision to remove one ovary even if the other is normal. In many cases, resection of a pathologic ovary leaves enough functioning tissue to give the patient two functioning ovaries against the possible future ravages of time.

The following case falls into a similar category.

G M a 26-year-old woman had been married 5 years and had been unsuccessful in becoming pregnant. An extensive abdominal operation was performed by another surgeon in 1942. The patient was informed that part of an ovary had been removed during this operation. Subsequently, she continued to have severe pain during the menstrual periods. Examination in January, 1944 disclosed enlargement of the left ovary to nearly four or five times the normal size. On January 19, 1945, I performed lysis of intra abdominal adhesions, a left salpingo-oophorectomy and partial resection and repair of the right ovary.

The left ovary was enlarged about four times the normal size, owing to "chocolate" contents. A presacral neurectomy and excision of multiple endometriomas were done. The right ovary contained a chocolate cyst, which was resected.

The pathological report disclosed "chronic perisalpingitis and peri-oophoritis, and endometrial cysts of the ovary."

This patient was urged to try for pregnancy soon after her discharge from the hospital and on April 4th, she had her last regular menstrual period. On January 18, 1946, after a test of labor this patient was delivered (x ray measurements — diagnosis of disproportion), by low cervical cesarean section, of a normal, male baby weighing 6 pounds 6 ounces. At operation the remaining right ovary was examined. It appeared normal.

## DISCUSSION

In these cases conservative ovarian surgery was practiced. The older textbooks invariably advise the complete removal of ovaries in such cases. If this advice had been followed in the cases described above, the patients would have lost completely the opportunity of becoming pregnant, would have suffered sudden surgical menopause and would also, as a result of these changes, have had difficulty in their domestic welfare.

Reference has been made to "older textbooks." As a matter of fact, even recent articles in the medical literature seldom allude to the use of conservative surgery. This paper, therefore, is written as a plea that the surgeon consider carefully his decision to remove ovaries, that he remember the dire consequences from the removal of both ovaries in young women, and that he preserve as much ovarian tissue as possible.

## SUMMARY

Four cases in which both ovaries were not removed, even though the tissues were pathologic, are cited.

Two cases of bilateral ovarian dermoid cysts are described. In both, dime-sized portions of tissue were preserved. One patient, who married later, was subsequently delivered of 3 normal children.

Two cases of endometriosis are reported, both with endometrial implants and involvement of both ovaries. In each, one ovary was removed. The remaining ovary was partially resected. Both patients were subsequently delivered of normal healthy babies and had regular painless periods after these deliveries.

In the treatment of a large number of women over a period of seventeen years, conservative surgery has been practiced in numerous cases, and the final results have been most gratifying.

The 4 cases described were chosen as the most suitable to drive home the point that conservative ovarian surgery is possible and ultimately pays large dividends to the patient.

## CLINICAL NOTE

## THORACIC TENDERNESS IN PULMONARY INFARCTION

JOHN GODFREY, M D \*

BOSTON

**D**URING the last decade, steadily increasing attention has been paid to the early diagnosis, in both medical and surgical cases, of phlebothrombosis and thrombophlebitis. Earlier diagnosis and prompt treatment with the anticoagulants, or by venous ligation, have appreciably reduced the number of unfortunate cases in which the patient, making an uneventful convalescence, suddenly succumbs to a pulmonary embolism. However, in spite of routine daily examinations of the legs and scanning of the chart, the first evidence of such a process is all too often observed too late.

Boyd<sup>1</sup> divides pulmonary emboli into three classes: large emboli occluding a main artery and causing death with respiratory distress, medium-sized emboli producing physical signs of an infarct; and small emboli causing symptoms but not physical signs of infarction. It is the purpose of this communication to describe a physical sign that occurs in the small emboli in the third classification.

It is important to make the diagnosis of pulmonary infarction and institute treatment immediately after the episode has occurred, since there is no assurance that a second, and perhaps fatal, embolus will not occur at any time. Yet x-ray study cannot be expected to confirm the diagnosis for nearly twenty-four hours, and physical signs in the lungs are totally absent if the embolus is small and may be equivocal if it is present.

An early and striking finding in 4 well established cases of pulmonary infarction occurring postoperatively, and in 1 equivocal case occurring in an orthopedic patient, has been marked tenderness of the chest wall, approximately over the site of infarction. This tenderness in all cases was severe enough to cause the patient to cry out and flinch if moderate pressure were applied. It was present in 1 case as early as six hours after the initial onset of pleuritic pain and disappeared gradually in from forty-eight to seventy-two hours. The area of tenderness varied in diameter from 2.5 to 20 cm, presumably depending on the extent of the underlying pleuritis, and in each case a sharply demarcated point of maximum tenderness could be demonstrated in one of the intercostal spaces.

Brief abstracts of the pertinent data in 5 cases follow.

**CASE 1.** A 39-year-old housewife developed severe pleuritic pain in the right anterior portion of the chest 11 days after

\*Formerly, fellow in medicine, Lahey Clinic.

choledochostomy. The temperature rose to 100°F. Examination revealed exquisite tenderness in the right anterior portion of the chest with point tenderness in the sixth interspace in the anterior axillary line. The lungs were clear, and x-ray examination of the chest was negative. There was tenderness in the calves of both legs with a positive Homans sign on the left. A bilateral femoral ligation was performed.

**CASE 2.** A 20-year-old girl developed acute deep thrombophlebitis of the left leg on the 8th day after ileostomy for ulcerative colitis. This was treated by repeated paravertebral blocks, caudal blocks and heparin-dicoumarol anticoagulant therapy. On the 9th postoperative day, a mild pleuritic pain developed in the right anterior portion of the chest without other symptoms. Physical examination showed point tenderness in the sixth interspace in the anterior axillary line, but the lungs were clear and x-ray study of the chest was negative. On the following day a friction rub was audible in the involved area.

**CASE 3.** Eight days after a cholecystectomy, a 53-year-old housewife developed pleuritic pain in the right posterior portion of the chest that was so mild that she did not mention it for 24 hours. There were no other symptoms. The temperature was 99°F, and the respirations 28. There was definite tenderness over the right lateral and posterior portions of the chest with point tenderness. There were suppressed breath sounds and moist rales in this area. X-ray study of the chest was interpreted as showing atelectasis. There was questionable tenderness over the left femoral vein. Anticoagulant therapy was instituted.

**CASE 4.** A 25-year-old man, scheduled for exploratory laparotomy, had operation delayed for 10 days pending evaluation of deep tenderness noted first in the right calf and later in the left calf. There was no elevation of vital signs, and Homans sign was negative. However, on the 1st postoperative day there was gross hemoptysis. On the 2nd postoperative day the patient noted severe pleuritic pain in the right anterior portion of the chest. There was extreme tenderness in this area. The temperature rose to 102°F, the pulse to 110, and the respirations to over 30. X-ray examination showed consolidation of the right lower lobe. Anticoagulant therapy was instituted.

**CASE 5.** A 73-year-old woman had been in bed 3½ months, after an open reduction and nailing of a fractured hip, when she developed a sharp pleuritic pain in the left anterior portion of the chest, which lasted for 3 days. There was point tenderness in the fifth interspace in the anterior axillary line, but physical examination was otherwise negative, with no signs of phlebothrombosis. X-ray study of the chest 3 days later was negative. No therapy was instituted, and no further episode occurred.

It is significant that in none of the cases did there appear the combination of symptoms and signs that are generally considered typical of pulmonary infarction — that is, cough, hemoptysis, pleuritic pain, fever, increased respiratory rate, distant bronchial breath sounds, moist rales and x-ray evidence of infarction. Two cases showed pleuritic pain and thoracic tenderness alone, whereas another had a transient friction rub in addition that could easily have been missed. Only 2 cases revealed changes in the lung by physical and x-ray examination.

It is also significant that in 1 case the diagnosis of pulmonary infarct was not considered during the hospital stay, and that in another, a delay of several hours ensued before the true nature of the episode was appreciated and ligation performed. In a third case the symptoms were so insignificant that the patient did not mention them until twenty-four hours had elapsed.

The significance of this sign (thoracic tenderness), which is certainly neither new nor unknown, is apparently not widely appreciated. A survey of the standard textbooks of medicine and physical diagnosis, as well as various systems of medicine and texts on differential diagnosis, failed to elicit any reference to the sign. A review of the literature for the last ten years, however, resulted in the finding of one paper on the subject. McMillan,<sup>2</sup> in 1942, described extreme tenderness on light fist percussion over the affected area in cases of pulmonary infarction and reported 14 cases. He considered this sign

of great value in the differentiation of pulmonary infarction and pneumonia.

It is suggested that the presence of chest tenderness in connection with a pleuritic type of pain in the absence of trauma be considered suggestive of pulmonary infarction, even in the absence of supporting symptoms, signs or x-ray changes and that treatment be undertaken on that basis.

## MEDICAL PROGRESS

### SYPHILIS

G MARSHALL CRAWFORD, M.D.\*

BROOKLINE, MASSACHUSETTS

AT THE time of this writing it is approximately four years since the publication of the first report on the use of penicillin in the treatment of syphilis.<sup>1</sup> The remarkable efficacy of this drug in combating man's most crippling venereal disease is attested by the fact that in so short a time it has become accepted as standard therapy for syphilis. A vast effort has been expended in widespread and well organized research projects, both experimental and clinical. From ten to twenty years are required to evaluate properly the therapeutic results of any approach to syphilis in all respects except immediate effects on fresh infections. The response of early syphilis to penicillin has been so dramatic, however, that the acceptance of this drug is now granted. Its long-term results will have to await further and prolonged observation periods. Despite this remarkable new weapon and the extraordinary success achieved by the military forces during the war, the trend of venereal-disease incidence is again on the rise.

#### PUBLIC HEALTH

The advent of penicillin has resulted in an increase of the treatment of syphilis by physicians engaged in diverse types of practice. This antibiotic has simplified the treatment of syphilis to the point where it can be administered by most practicing physicians with a modicum of danger. Anyone except those in more remote specialties can treat the disease, provided their plan of therapy is adequate. Two main pitfalls enter into the problem at this point. With such increased ease of therapy, a natural hazard is the possibility of treatment

without accurate diagnosis. Cases of this sort have come to the attention of most syphilologists in which physicians with undoubted skill in their own fields of work have too readily assumed the diagnosis of syphilis and instituted treatment. There are few diseases with more sociologic import than syphilis, and one should exert extreme care in making the diagnosis, entirely aside from the medical implications. Syphilologists, more than other physicians, are extremely loath to make a diagnosis of syphilis without unequivocal evidence, this applies particularly to the primary and secondary stages of the disease. The second and possibly even greater hazard in the treatment of syphilis by physicians in general practice is the likelihood of employing insufficient dosage of penicillin. There are many facets to this problem that have not been worked out satisfactorily, and programs of therapy are still constantly being changed. Penicillin causes so comparatively few reactions that overdosage is far less hazardous than with any other treatment for syphilis. Consequently, it is better to err on the side of giving more penicillin than is thought necessary, rather than using insufficient quantities. This will obviate the likelihood of infectious relapse that might easily go unrecognized until many more persons had been infected. It should not only increase the percentage of immediate "cures" but also go far toward preventing the late serious crippling sequelae of syphilis. The economic burden already entailed by syphilitic inmates of mental institutions is far too great. During the decade 1935-1944, inclusive, first admissions to mental hospitals in the United States due to syphilis, of all varieties comprised a rather high percentage, exclusive of the

\*Adjunct head, Department of Dermatology, Harvard Medical School; acting head, Department of Dermatology, Massachusetts General Hospital.

### *Statistical Trend*

The remarkable accomplishment of the military forces during the war in keeping the incidence of venereal disease lower than any previous wartime rate in history is well known. A survey of venereal diseases among the civilian population during the same period shows a trend that is not so encouraging.<sup>3</sup> The cases of syphilis diagnosed in the states and territories during the years 1941-1947, inclusive, and excluding all military sources, reveal a different state of affairs. During the first two years of the war, cases of syphilis reported for the first time among civilians increased steadily to a maximum of 576,000 in 1943. For the next two years, there was a significant drop, a low of 368,000 cases being reached in 1945. An increase of about 0.5 per cent, which was not significant, took place in 1946, and one of somewhat over 5 per cent was reported for the first half of 1947, which is a strong indication for the need of more urgent control measures. The majority of this elevation in rate took place in primary and secondary cases, pointing to the existence of reservoirs of readily available fresh disease. When further broken down, the statistics show a steady decrease in the number of late, late latent and congenital cases of syphilis during the same period of six years. These figures reflect the effectiveness of control measures that were carried out by both the armed forces and the United States Public Health Service. This downward trend in late crippling disease and congenital infections will not be maintained if the incidence of fresh infections continues to rise.

A purely military survey indicates a similar but more pronounced trend.<sup>4</sup> The report shows that a distinct increase in venereal disease became evident in the navy soon after VJ Day. This was reflected in all naval districts and made venereal disease the outstanding factor in morbidity at that time. The most marked increase was apparent in noncontinental areas and ships, in continental naval districts the increase was equally consistent, though slower. Naval personnel in the West Pacific area sustained the greatest increase of venereal disease, the rise in rate multiplying more than elevenfold in one year. Although military personnel has been drastically reduced since the war, there has been no relaxation in the attempt to control venereal disease in that quarter. A working agreement has been reached between the Army, Navy, Coast Guard, Federal Security Agency and American Social Hygiene Association, establishing peacetime relations in venereal-disease control.<sup>5</sup> In addition to the maintenance of military measures, this includes procedures by all public-health departments directed toward case finding, diagnosis, treatment and repression of sources of infection among the civilian population. The armed forces will continue to declare "out-of-bounds" establishments

that serve as places of pickup. The United States Public Health Service will continue to assist and co-operate with public institutions and scientists in the conduct of research and experiments relating to diagnosis, treatment and control of venereal disease.

There has been an impression that in recent years syphilitic infections among the teen-age groups have constituted an increasing proportion of the problem of venereal-disease control. It has also been thought that the vast numbers of men in military service who were concentrated in encampments had a pronounced influence on venereal-disease rates. An analysis of statistical data concerning patients admitted to public clinics for early syphilis from 1941 through 1944 contradicts these impressions.<sup>6</sup> The analysis was limited to females and indicated that a shift into the teen ages has not been nationwide and that a tendency toward an earlier age of infection among white females was most pronounced in the presence of an increasing civilian population, particularly in areas of war-boom industrial concentration. Increasing military populations seemed to have little or no tendency to be associated with an increased proportion of teen-age infection among white females, presumably because of active control measures within the armed forces.

### *Control Measures*

There are many communications giving evidence of the awareness of public-health authorities of the increased menace of syphilis. Information regarding sources of infection has always been difficult to obtain. Self-interview forms have been devised to elicit information from reticent patients.<sup>7</sup> These forms include pertinent advice regarding the danger and infectiousness of venereal disease and thereafter request information regarding sex partners, but do not require the patient to sign his name. The information is thus confidential, and co-operation is sometimes more readily obtained. Studies of epidemiologic activity on syphilis contacts reveal that approach by telegram, by visits to the patient and by letter all have their value in persuading suspects to report for examination.<sup>8-10</sup> Telegrams sometimes have a surprisingly effective result and may be even more efficient than a direct personal visit. Registered mail is obviously more impressive than ordinary letters. Personal visits take time and are expensive and comparatively slow, both in finding contacts and in returning patients to treatment. Compulsion is an effective but also an expensive method of case holding and cannot be used until a considerable time has elapsed since the patient's last treatment. Telegrams and registered letters are to a large extent effective in solving these problems. Compulsory attendance for an examination, for treatment or for those who have permitted therapy to lapse should be avoided if

possible Co-operation is not obtained by compulsion, and compulsion should be used only as a last resort.

Postgraduate instruction in venereal-disease management is available in almost every medical center of the country. Postgraduate refresher courses are being organized throughout practically every state. The practicing physician and public-health officer should be brought up to date regarding new methods of treatment and recent refinements in the diagnosis of venereal disease. Diagnostic and consultation services are available to physicians in nearly every community through clinics, medical schools and public-health agencies. Training or refresher instruction can be obtained either on an individual or a group basis, and if practicing physicians avail themselves of these opportunities many unfortunate errors can be avoided, simultaneously, an increased efficacy of venereal-disease control can be attained.

The importance of nurses in venereal-disease control is being more properly emphasized. The value of a nurse as a case finder cannot be overestimated.<sup>11</sup> An alert nurse in clinic, school, industry or on visiting-nurse duty can find many opportunities in her daily routine to serve as a case finder. Patients will sometimes more readily confide in a nurse than a physician and with proper interviewing may reveal contacts that would otherwise be undiscovered. The industrial nurse's responsibilities in venereal-disease control have increased since the end of the war.<sup>12</sup> The interests of management and labor in a good educational program are being stimulated. The industrial nurse fits neatly into this program both from the educational standpoint and in assisting case-finding measures. She has many opportunities for personal counseling with employees in family health problems and can include many phases of venereal-disease control. In a large clinic the nurses are responsible to a great extent for the atmosphere of the clinic and are an important factor in obtaining the co-operation of the patients.<sup>13</sup> The nurse may serve as a liaison between the doctor and the patient and between the patient and his family when trouble arises. She can often explain to the patient the physician's recommendation for the need for treatment of himself as well as contacts. Nurses may have more tact and ingenuity than physicians in many instances. Their responsibility in the education of the patient is of great importance. This is especially true of the public-health nurse in rapid-treatment centers, where the nurse is of inestimable value.<sup>14</sup>

#### *Morbidity and Mortality*

Among 3970 autopsies performed at the Yale University School of Medicine between 1917 and 1941, 380 showed evidence of syphilitic infection.<sup>15</sup> Of these patients 198 (52.1 per cent) had never received treatment. Anatomic lesions of syphilis were found in 77 (38.9 per cent) of these untreated

patients, but in only 46 (23.2 per cent) was death considered to have been due primarily to syphilis. One hundred and twenty-one patients revealed an absence of anatomic lesions of syphilis, and in 35 cases the serologic tests for syphilis were negative during the last hospital stay. The 77 untreated patients with post-mortem changes revealed 88 cardiovascular lesions, 8 lesions of the central nervous system and 10 other types of lesions. These results closely agree with the observations of Bruusgaard,<sup>16</sup> who was the first to report an authoritative series of untreated patients examined pathologically years later. The current report is an important study, and it should be read in the original by all syphilologists.

A survey by the Bureau of the Census of vital-statistics rates in the United States reveals a steady decline in the death rate from syphilis from 1938 to date.<sup>17</sup> There has surely been no de-emphasis of syphilis as a cause of death nor any decrease in the ability of doctors to recognize it during this time. Therefore, it is believed that this decline is a real one that can be attributed to the venereal-disease-control program. Evidently the treatment schedules advocated in the last few decades have been to good effect. As might be expected, the decrease in infant mortality due to syphilis has been even more pronounced. A survey of the most recent communications on the mortality of syphilis has given rise to formulation of a policy regarding the eligibility of syphilitic persons for life insurance.<sup>18</sup> This study and its recommendations regarding eligibility for insurance have been carried out by eminent syphilologists rather than the usual actuarial approach of insurance companies. It is of primary value and interest to the insurance actuaries but contains information valuable to anyone dealing with syphilis. The various types of the disease are classified regarding insurability, adequacy of treatment and probationary periods required after treatment before insurance should be granted.

#### EXPERIMENTAL STUDIES

##### *Penicillin in Oils*

Although penicillin in peanut oil and beeswax has been under study for some time, a recent report indicates that it may not be the best combination for delaying absorption of the antibiotic.<sup>19</sup> Injections of calcium penicillin of high potency suspended in hydrogenated cottonseed oil were found to maintain a penicillin level of 0.1 unit per cubic centimeter of blood for at least six hours in 80 per cent of cases, whereas in the beeswax-peanut-oil mixture it maintained that level in only 66 per cent. Hydrogenated oil delayed the absorption of penicillin more than the plain oils in all the various diluents tested. Undoubtedly, a good deal more work must be done along these lines before the best preparation is ultimately identified.

In experimental syphilis in rabbits, the effect of penicillin in peanut oil and beeswax has been compared with penicillin administered in isotonic solution of sodium chloride<sup>20</sup> The oil-wax suspension was definitely more therapeutically effective in the treatment of syphilitic orchitis of rabbits. When a single minimum curative dose of penicillin was employed, the oil-wax suspension was approximately ten times more efficient. When a single daily intramuscular injection was used for eight days in succession, the oil-wax suspension of penicillin required a minimal curative dose approximately one fifth as large as the saline solution. This work has been confirmed by other observers, who obtained essentially comparable figures<sup>21</sup> The curative dose of penicillin, whether in aqueous solution or oily suspension, varied with the number of injections into which treatment was divided. Penicillin in aqueous solution had to be subdivided into two to fourteen times as many injections as the oil-beeswax suspension to be equally effective. The superiority of the oil and wax suspension was particularly striking in schedules involving relatively large injections. The smaller the individual dose of penicillin, the less pronounced was that margin of superiority.

#### *Penicillin and Adjuvant Measures*

A large number of combinations of penicillin with heavy metals, arsenic, hyperpyrexia and other measures have been undergoing experimentation. The use of penicillin and bismuth in the treatment of experimental syphilis of rabbits has been found highly effective and safe with a minimum of reaction<sup>22</sup> A fat-soluble preparation of penicillin in the form of methyl ester was employed in the same fashion and seemed even more effective in its combination with bismuth, syphilis in rabbits required lower doses for cure, and the method was then applied to human beings, with equally satisfactory results<sup>23</sup> Prolonged periods of observation will be necessary in all these studies to ascertain long-term effectiveness. Confirmation of the value of combined therapy was not long in appearing, however, and the use of oxophenarsine hydrochloride combined with penicillin was likewise found of considerable value<sup>24</sup> A different type of bismuth salt was employed with just as satisfactory results. Oxophenarsine hydrochloride by both intravenous and intramuscular injection showed decided synergistic or adjuvant therapeutic effects in the penicillin treatment of syphilitic orchitis of rabbits. Bismuth subsalicylate is the most common salt of that metal to be employed in the treatment of syphilis. Its toxicity and therapeutic efficiency have recently been compared with those of two other bismuth compounds<sup>25</sup> The three bismuth compounds proved similar in therapeutic efficacy with generous margins

of safety. There is therefore no indication for the departure from general usage of the bismuth salicylate suspended in oil. All three types of bismuth preparations studied were mol for mol from one half to two thirds as active as Mapharsen in the treatment of experimental syphilis of rabbits. The margin of safety for the oily suspension of the subsalicylate was between six and eight times greater than that between effective and toxic levels of Mapharsen.

A new drug, Caronamide, is now being studied with the purpose of increasing penicillin plasma concentrations in man<sup>26</sup> This substance, when given orally to patients receiving penicillin, produced a physiologic and reversible inhibition of the excretion of this antibiotic, which increased the concentration of the penicillin in the plasma. Although there is not yet general agreement whether the maintenance of a constant level of penicillin plasma concentration is more desirable than the attainment of intermittent high levels, there is at least a need for high concentration of penicillin at certain times. Caronamide, when administered orally, elevates the penicillin plasma concentration from two to seven times, after either the oral or parenteral administration of penicillin, and should have great therapeutic usefulness in the treatment of conditions that require high penicillin blood levels. It is now being applied to the therapy of patients. Extensive laboratory investigation of the physiologic, pharmacologic, toxicologic and bacteriologic properties of Caronamide have justified its clinical use. The action of this drug is to inhibit the elimination of penicillin at the level of the renal tubules. The effectiveness of Caronamide is said to depend on a "substrate competition between penicillin, which is excreted by the tubules, and Caronamide, which is essentially refractory to excretion by that transport mechanism."

The therapeutic efficacy of penicillin *in vitro* has been shown to increase with temperature<sup>27</sup> Many syphilologists have been utilizing this fact in the combined treatment of neurosyphilis with penicillin and hyperpyrexia. A report has now appeared regarding the laboratory confirmation of this fact in experimental infections in rabbits<sup>28</sup> In the treatment of early syphilis in rabbits the therapeutic action of penicillin was strikingly enhanced by a simultaneous increase in body temperature, evidenced by the fact that the effective dose of penicillin was thereby reduced to one tenth of its usual level. The combination of fever with penicillin is neither feasible nor desirable, however, for the treatment of early syphilis in man. Penicillin therapy may be supplemented by bismuth or Mapharsen, which do not carry the risk of fever therapy and require considerably less expenditure of time and money. In neurosyphilis, however, the situation is quite different. penicillin alone may not suffice, and the

advantages of fever therapy are already well recognized. Whether the hyperpyrexia exerts its own effect or serves also to enhance the spirocheticidal activity of penicillin, their use in combination should yield results exceeding those hitherto obtainable.

### Experimental Reinfection

The question of reinfection vs. relapse has been a most controversial one since the advent of penicillin with its rapid eradication of lesions and apparent "cure" of early syphilis. Recurring evidence of clinically active disease after penicillin therapy has been variously interpreted as relapse or reinfection, depending upon the observers' evaluation of the history and symptoms. A relapse might thus be a treatment failure. On the other hand a reinfection could be used as a criterion of cure, or possibly of superinfection. A study of experimental syphilis in the rabbit has been conducted to determine what incidence of reinfection could be produced within ten days of the completion of adequate penicillin therapy.<sup>19</sup> Acute syphilis in rabbits was cured in three days with penicillin therapy, reinoculation was then attempted ten days after treatment had been completed. Twenty-seven per cent developed dark-field-positive chancres at the sight of reinoculation, and the remaining 73 per cent developed a symptomless infection confirmed by positive lymph-node transfer. Untreated rabbits with acute syphilis, reinoculated with a homologous strain of spirochetes at the same time period as the treated animals, did not develop clinical evidence of reinfection. It appears from this experiment (in which the second inoculation was introduced before the initial lesions had completely healed) that symptomatic or symptomless reinfection may take place before the disappearance of either the original clinical symptoms or the seropositivity of the host. This explains the so-called "ping-pong" syphilis, which has been noted in some patients with early syphilis treated with penicillin, in which a repeated interchange of infection occurs between two people with the same strain of *Treponema pallidum* (*Spirochaeta pallida*). The human body does not have time to produce a tissue immunity when the infection is eradicated so quickly. A symptomless reinfection may occur with a clinical and laboratory pattern resembling one of true serologic relapse in untreated animals or human beings. There is at least an immunity that lasts for a varying period and prevents reinfection in untreated cases.

### Penicillin Resistance

It has been suspected that penicillin-resistant strains of *Tr. pallidum* might appear. Earlier work with repeated culture passages through mediums containing substerilizing concentrations of penicillin

did not show evidence of increased resistance to penicillin.<sup>20</sup> Further experimental evidence has now appeared from work with syphilis in rabbits.<sup>21</sup> There was no evidence that *Tr. pallidum* acquired any resistance to penicillin after three consecutive passages through the testicles of rabbits treated with subcurative amounts of commercial penicillin. After the final passage the last group of rabbits was given a minimal curative dose of penicillin, and total cure was confirmed by lymph-node transfer. If this is true of the human disease it is exceedingly encouraging, since up to now almost every chemotherapeutic or antibiotic approach to human infection of any sort has sooner or later encountered resistant strains of organisms, regardless of the infection.

### Synthetic Penicillin

The complexity of processes required for the production of penicillin naturally led to attempts at synthetic development of this antibiotic. Synthetic penicillins have been produced independently in the United States and Great Britain as long ago as 1944.<sup>22</sup> Because of the obscurity of reaction mechanism, the synthesis at the present stage of development cannot be used as proof of the structure of penicillin. Improvement in the methods of synthesis have not progressed sufficiently to make commercial production practicable. It may be possible, however, to make new penicillins, which might possess even more desirable therapeutic properties.

### Streptomycin

With the advent of another wonder drug, streptomycin, it was natural to expect quick investigation of its possible effect on syphilis. It was found that the smallest amounts of streptomycin that cured syphilis in rabbits were more than three thousand times greater than the quantity of penicillin G required for effective sterilization of the infection.<sup>23</sup> The use of streptomycin for syphilis is obviously impracticable. Subsequent study of the same problem by other investigators was even less encouraging.<sup>24</sup> Still further work pointed to the possibility that streptomycin has no actual effect on syphilis.<sup>25</sup>

### Prophylaxis

In spite of education, various public-health attempts at control measures and new effective methods of therapy, the vagaries of human nature will probably always leave a place for prophylactic measures in the prevention of syphilis. The latest attempts to create effective prophylactic measures have been concerned with the use of propylene glycol solutions and ointments of various arsenox-

ides<sup>36</sup> Aqueous solutions in dilute soap were also employed. All these preparations had an encouraging prophylactic effect in preventing syphilis in rabbits, the ointments being the least useful regardless of the type of base employed. When infection was attempted through normal skin the soap solutions were highly effective prophylactic agents. If direct access was provided to the blood or lymph channels, all the prophylactic measures were largely ineffective. The application of these principles to the prophylaxis of the disease in men would encounter so many variables that an assay of their value would be exceedingly difficult. The length of time during which the organism might remain accessible to the prophylactic drug is unknown. The infectiousness of the exposure would vary. The time interval between the exposure and the use of prophylaxis, as well as the skill of the prophylactic application, would make the results of dubious significance.

### Staining Method

Numerous methods of staining *Tr. pallidum* have been reported in the past, but most of these require techniques that are not readily available and often too complicated for convenient use. A reasonably quick staining method that may be more generally applicable has been described.<sup>37</sup> The entire process is said to take only one minute, but the description will not be repeated here. Its usefulness is somewhat limited since dark-field examination is generally available and is usually more reliable. In some cases in which exudate is profuse and relatively uncontaminated serum cannot be obtained, staining methods would be of use.

### IMMUNITY IN SYPHILIS

Human beings do not possess natural resistance to syphilis, but some degree of immunity develops in man as a result of syphilitic infection. The mechanism of the defense process is still unknown. It is probably a tissue or cellular reaction, since the existence of humoral antibodies against syphilis have not been demonstrated. Numerous attempts to induce active or passive immunization against syphilis in man and animals have failed to produce any significant results. The relation of the positive serologic reaction to the organism's capacity to produce antibodies against spirochetes is not clear. Immunity at any stage of the disease is never absolute, but only relative. Untreated infection with syphilis confers on the human being immunity that prevents natural superinfection but does not protect him against massive artificial superinfection. Intensive treatment of early syphilis is in all probability capable of curing the disease. Such treatment abolishes all immunity that is in the process of development but does not endanger the patient if

it is strong enough to eradicate the infection completely. Inadequate antisyphilitic therapy will seriously impair the natural defensive mechanism, and the patient will be left both without a cure and without defense. This often leads to neurorecurrences, therapy-resistant relapses and precocious tertiarism. One student of the problem believes that animals treated in the late stages are biologically cured and at the same time actively immunized because they were thoroughly infected for a sufficiently long time.<sup>38</sup> A patient might thus be completely cured and yet remain refractory to natural reinfection. The reinoculation test (reinfection) is not believed by others to constitute a reliable criterion of cure in treated animals.<sup>39</sup> A symptomless infection is held to be possible in these animals, and this could be determined only by removal of tissue from treated animals at appropriate intervals after cessation of treatment and inoculation of that tissue into normal animals. These writers further believe that immunity is a special form of allergic hypersensitiveness. It is claimed that the whole course of untreated syphilis can be explained on the basis of allergy. The chancre is thus regarded as an allergic defensive measure that marks the beginning of the organism's altered reactivity to reinfection. The cutaneous manifestations of secondary syphilis are also thought to be manifestations of an allergic defense mechanism. The tertiary stage of the disease frequently shows severe local manifestations, during a phase in which the number of spirochetes is small, and these events are regarded as signs of a high degree of allergy. It is possible that a new approach toward understanding the nature of immunity in syphilis will be possible if further study confirms the preliminary demonstration of complete sterilization by penicillin therapy of animals experimentally infected with syphilis.<sup>39</sup>

A study of the same problem in infected rabbits treated after periods of three or four months with arsenobenzol injections led to the conclusion that immunity cannot depend on the persistence of parasites but must be an acquired one that developed at least three months prior to the treatment.<sup>40</sup> Attempts at reinoculation, as well as tissue inoculations from the treated animals, were confirmatory. Only 3 per cent of the reinoculated animals developed clinical syphilis, and 6 per cent presented symptomless reinfection. It was further shown that the immunity persisted in varying degrees for approximately a year before it decreased appreciably. Still another author proposes the term "reactivation" for infections such as syphilis, in which an "immunoallergy potential" is all that remains of an infection and in which reinoculation does not produce reinfection or superinfection.<sup>41</sup> He believes that parts of the syphilitic process may be evoked by superinoculation in such cases, because the first course of events in an infection cannot be exactly repro-

duced while some degree of allergic state or immunity persists. It is further stated that in absolute cure neither spirochetes nor potential remain.

It is obvious that thorough disagreement if not confusion exists rather generally regarding the problem of immunity in syphilis. Perhaps the best lesson to be learned from this discourse is the fact that a small amount of treatment in early syphilis, which is inadequate to eradicate the infection, is worse than none. It will interfere with the body's own defensive mechanism, fail to eliminate the infection and leave the patient worse off than nature alone would have left him. Perhaps his untreated infection will be discovered at some later date during the so-called "hyposensitive phase," when it may be at least arrested by therapy, before he reaches the hypersensitive or allergic state in which the explosive tertiary tissue reactions take place.

(To be continued)

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

#### CASE 34031

##### PRESENTATION OF CASE

*First admission* An eighteen-year-old girl was admitted to the hospital with dyspnea

Three years previously, following the death of her mother with pulmonary tuberculosis, she became run-down and developed cough, sputum and hemoptysis. An x-ray film showed cavitation in the right apex, and she was hospitalized in a sanatorium for two years. While she was at the sanatorium a good collapse was obtained by pneumothorax, and she gained weight and became symptom free. The pneumothorax was continued at intervals after discharge. Three months before admission, following a refill of air, she developed a persistent dry cough, fever and night sweats.

Physical examination revealed a well developed, well nourished girl with signs of fluid in the right side of the chest.

The temperature was 99 to 100°F, the pulse 90, and the respirations 20.

Examination of the blood and urine was negative. An x-ray examination of the chest showed a pneumothorax on the right, the fluid level lying opposite the seventh interspace posteriorly. The right lung was about three quarters collapsed, and no cavities were seen. The left lung field was clear. The heart was displaced.

A chest tap yielded purulent fluid. Ordinary aerobic and anaerobic cultures were negative, a guinea-pig inoculation was positive for tuberculosis.

The temperature and pulse subsided, and the patient was discharged eight days after admission. Pneumothorax was permanently discontinued.

*Final admission* (nine years later) The patient was readmitted because of dyspnea.

For many years she had felt well. She had married and had had a normal pregnancy. Two years before readmission she developed a lump in the right breast. A simple mastectomy was done at an outside hospital, and the pathological report was carcinoma (Grade II). She then received fourteen radium treatments. Six months later she noted a lump in the right axilla, and a complete axillary dis-

section was done. She made a good recovery and worked as a cook until four months before re-entry. At that time she began to have pleuritic pains in the bases of the lungs and shoulders, shifting from one side to the other, associated with a temperature of 100°F, cough with some expectoration of white material, anorexia, nausea and vomiting and weight loss. In the past month there was also rapidly progressive dyspnea, weakness, dizziness and a temperature of 98 to 101°F.

Physical examination revealed a well nourished, orthopneic woman. There were flatness and absent breath sounds in the lower half of the right side of the chest.

The temperature was 99°F, the pulse 110, and the respirations 20. The blood pressure was 134 systolic, 80 diastolic.

Examination of the blood revealed a hemoglobin of 11.5 gm and a white-cell count of 12,800, with 89 per cent neutrophils. The urine and stools were normal. A Congo red test showed 60 per cent retention of the dye in one hour.

An x-ray film of the chest showed the right lung expanded to only half the thoracic cage and covered by a thick layer of organized pleural exudate (Fig 1). Fluid and air filled the remaining portion of the chest cavity, the fluid level being at the ninth rib posteriorly. There was also considerable thickening of the parietal pleura. It seemed that only the upper lobe of the lung contained air, the remaining portion of the lung being drowned. The mediastinum was not displaced. The left lung was clear.

A thoracentesis was done, and 300 cc of thick, turbid fluid was removed. Ten days later the fluid had reaccumulated, and another 200 cc was removed. Ordinary cultures of this fluid showed no growth. Two weeks later the patient complained of a constant aching epigastric and left-upper-quadrant pain unrelated to food. Nausea and vomiting became more frequent. A large, poorly defined epigastric mass was palpated. A peritoneoscopy was unsuccessful because of omental adhesions to the liver. This operation was followed by subcutaneous emphysema and persistent drainage of ascitic fluid through the opening. A plain film of the abdomen showed little, if any, air in the peritoneal cavity, most of it being distributed through the various layers of the anterior abdominal wall. The soft-tissue contours of the belly were obscured. A gastrointestinal series showed a normal esophagus. The stomach was displaced anteriorly and to the left by an epigastric mass, which was in the position of the left lobe of the liver. No evidence of intrinsic disease of the stomach or duodenum was found. Three weeks later there was pain low in the back, radiating down both legs.

The patient lost ground rapidly. Prior to death she was slightly icteric and had a miliary pustular purpuric rash over the upper limbs and shoulders. She died five weeks after readmission.

## DIFFERENTIAL DIAGNOSIS

DR. DONALD S. KING This is the story of a woman of twenty-seven who had a wasting disease of four months' duration, and this disease ran a febrile course. On physical examination there were two important findings: pleural effusion on the right and an epigastric mass. There was a history of two wasting diseases—tuberculous empyema and possibly generalized tuberculosis, and cancer of the breast with possible metastases. Both diseases can cause pleural effusion and abdominal fluid.

Did she have tuberculosis? Did she have cancer? Did she have both? One has to examine the three parts of the story. First, let us take the course of the disease. I stress the fact that it was a febrile course, and I consider that fact important. Very often when one follows the cases of known metastatic carcinoma from the breast with pleural effusion, temperature enters the picture and we wonder whether we are dealing with infection and not with a growth, but I do not believe that a persistent temperature for four months, as I assume this to have been, is quite consistent with cancer alone. To my mind, however, the febrile course favors tuberculosis. At the end pain occurred in the back and was referred down the sciatic nerve, but I think that it is too late to call that definite spinal metastases from the breast, although that is a common complication with such cancer. The slight icterus at the end and the milium pruritic lesions on the shoulders, I think, can be explained on either basis, perhaps slightly better as tuberculosis than cancer, but they are of no great significance.

DR. TRACY B. MALLORY Dr. King, would you like to see the temperature chart?

DR. KING Certainly. It seems that the patient was running only a slight temperature. She came in with a temperature of 101°F. Following that it was almost always above 99°F., occasionally 100°F. At the end the rectal temperature was 99 to 100°F., and finally she had a temperature of 104°F. This does not support my thesis too well. It was not a really febrile disease. I expected the chart to show a swing from 99 to 101°F. But I still think that the fever is a little more consistent with tuberculosis than with cancer.

There are two points about the pleural effusion. In the first place, the fluid is described as definitely thick and turbid, and a thick, turbid fluid is the fluid of tuberculosis and not the fluid of cancer with metastases to the pleura. I do not remember ever having seen anything except a fairly thin, straw-colored or bloody fluid with cancer of the breast involving the pleura. There is no report of guinea-pig inoculation at that time. It was nine years previously that the patient was known to have definite tuberculous empyema. At that time the pneumothorax, which she had been carrying for three years, was discontinued. We do not know how many

times the chest was tapped after that, and we do not know whether the lung re-expanded. We assume that it did. We dread the tuberculous empyemas, which may come with artificial pneumothorax, and that is one of the reasons why at present there is a slight tendency away from artificial pneumothorax treatment. This girl had had it nine years previously, and it looks as if she developed tuberculous empyema again.

May we see the x-ray films?

DR. STANLEY M. WYMAN The fluid level is probably intrapleural, as the record says. There is con-

FIGURE 1

siderable collapse of the right upper lobe. The right lower lobe cannot be identified. It is probably almost completely collapsed. The right breast is missing. I do not see any metastases, and I do not see any evidence of hilar or mediastinal nodes. This is the film taken after the first tap. It shows that the fluid level has decreased. There is a thin rind over the lung and along the wall of the thoracic cage.

DR. KING There is no description of the film taken before the chest was tapped. After the tap the patient had a small hubble of pleural air. Where the pleural air was coming from after nine years is hard to say. She may have developed a bronchial fistula, following which she again developed tuberculous empyema. So far as this film is concerned, it does not offer much to differentiate tuberculosis and cancer, except that I can explain the pocket of air better on the basis of tuberculosis with bronchial fistula than by cancer with pleural metastases. After she had been tapped the pleura presented a

different appearance. I am interested in the terminology. Dr Wyman called this a "rind," by which he means the thick layer of pleural exudate, which would have been called a "thickened pleura" five years ago. During the war Dr Wyman saw the surgeons "peel" off these exudates and leave a rather shiny pleura beneath. Later there may be organization of the pleural exudate and a condition more like a real "thickened pleura." In any case I think that the x-ray appearance of the pleura, both visceral and parietal, is more consistent with tuberculosis than with pleural metastases from cancer. The patient was a good candidate for metastases to the pleura, and extensive pleural thickening may be the result in such cases, but so far as the clinical course and the x-ray film of the chest are concerned, I am still in favor of tuberculosis.

The third point for consideration is the epigastric mass. In the x-ray report this is described as an ill defined shadow displacing the stomach anteriorly and to the left.

DR WYMAN. I assume that the location anteriorly was determined by the fluoroscopist. The stomach is certainly displaced to the left on both films. I cannot outline the definite mass on the film, and I cannot outline the abdominal viscera well because of the overlying gas in the abdominal wall. The gas is best seen in the lateral view.

DR KING. I suppose that during the peritoneoscopy they pumped air as they usually do and pumped it outside rather than inside, because of the extensive omental adhesions. At least we are told that there were adhesions. I do not believe that this shadow is the liver, but I want you to tell me what it is.

DR WYMAN. I cannot say that it is not the liver. I am rather inclined to think that it may be a slender tongue of liver tissue. The diaphragm is not elevated.

DR KING. I would like to attach this shadow to this one here and call them both liver. Is that possible?

DR WYMAN. It is hard to say that it is not.

DR KING. You do not help me much. The mass is in the position of the liver. Both lobes may be enlarged. All we know is that there were omental adhesions around the liver, and a mass. If we accept the diagnosis of tuberculosis, a mass involving a good many retroperitoneal lymph nodes is a good possibility. After peritoneoscopy fluid drained out through the peritoneoscopic wound. On this account I think that I should incline again toward tuberculosis, rather than cancer. Ascitic fluid can certainly develop with cancer because cancer of the breast often metastasizes to the peritoneum and there is drainage through the peritoneoscopy tap or puncture holes. But the evidence seems better for tuberculosis than cancer. I am still on the fence in deciding whether the mass was the liver.

There are two or three things that I might mention in closing. Amyloid disease may come into this liver problem. Amyloid disease was obviously under consideration when the Congo red test was performed. The test in this case was, in my opinion, normal. I recently heard Amberson, of New York, say that unless 100 per cent of the Congo red is absorbed from the blood by amyloid tissue, the test is of no value. That is a strong statement, but I think that it is probably true in this case that the test was not positive. If this had been a large amyloid liver I think that it would have absorbed more than 40 per cent from the blood serum. Dr Reuben Schulz, who has had a great deal of experience with amyloid disease, states that 20 per cent of all patients with tuberculosis autopsied at Middlesex County Sanatorium show amyloid disease. At Lakeville, where there is more extrapulmonary tuberculosis with osteomyelitis and so forth, the percentage is much higher. I have not seen a case for a year and a half. If this woman had tuberculous empyema for nine years she must have been a good candidate for amyloid disease. But I do not believe that we have evidence for tuberculous empyema over that period. Finally, if I make this diagnosis of tuberculosis, I am obviously on the spot regarding tuberculosis in the lungs. There is nothing that I can see in either of these chest films that looks like tuberculosis. The lower lobe that is mentioned as being "drowned," I do not believe is a drowned lobe in the sense that one ordinarily uses the term—that is, bronchial obstruction with infection beyond the obstruction. It is more to my mind an atelectatic lobe. What do you say, Dr Wyman?

DR WYMAN. I agree.

DR KING. I shall have to make a diagnosis of generalized tuberculosis, for I do not believe that tuberculosis of the pleura alone caused the death. It must have spread beyond the pleura to involve the bronchi and probably the mediastinal and retroperitoneal lymph nodes. In spite of the x-ray film, I believe that there was bilateral pulmonary tuberculosis. Did the patient also have cancer? I am voting against it. There is no proof. I think that she was a good candidate for neoplasm, and I am willing to admit that there are all kinds of loopholes. Out in Denver recently I saw a note on the wall of the clinical amphitheater saying, "A man learns 10 per cent of what he hears, 30 per cent of what he reads, 50 per cent of what he sees, and 90 per cent of what he does." I am going to add that he learns 100 per cent of what he does wrong in these clinicopathological conferences.

DR WYMAN. I should like to go on record a little more clearly regarding the liver. I believe that it may have been enlarged.

DR KING. That does not to my mind make the diagnosis of cancer. Dr Amberson also says that he found a good many fatty livers along with amyloid disease. Is it true, Dr Mallory, that an en-

larged liver in amyloid disease is due to fat and not amyloid?

DR. MALLORY I have not seen it often, but I imagine that it might occasionally be true

DR. REED HARWOOD The patient had icterus

DR. KING Yes, at the end she had slight icterus I do not know how much stress to put on it If one goes down the list of findings and symptoms in generalized tuberculosis it includes icterus But it would not help in differentiation of the two

#### CLINICAL DIAGNOSES

Metastatic carcinoma  
Tuberculous empyema

#### DR. KING'S DIAGNOSES

Pulmonary tuberculosis  
Tuberculous empyema  
Generalized tuberculosis involving mediastinal and retroperitoneal lymph nodes

#### ANATOMICAL DIAGNOSES

(Carcinoma of breast.)  
Metastases to lungs, liver, axillary, mediastinal and retroperitoneal lymph nodes, ovary and vertebrae  
Chylous ascites and hydrothorax, right

#### PATHOLOGICAL DISCUSSION

DR. MALLORY Autopsy showed widespread metastatic carcinoma. That may or may not be the entire answer. The liver was very much enlarged and full of metastatic carcinoma. There was also a very diffuse involvement of the lymph nodes of the mediastinum and up and down the aorta and retroperitoneal area, probably including the area of drainage of the thoracic duct. At the time of autopsy there was turbid fluid in both the abdomen and the cavity in the right side of the chest. Our impression of that fluid was that it was pseudochylous rather than purulent. There were very few cells found. At the time of death a guinea-pig inoculation of the pleural fluid had not been reported. Therefore, we did not include it in the abstract. This morning we sacrificed the animals, and they were entirely normal. On the other hand the cavity in the right pleura was encapsulated with thick, almost acellular collagen, which was in turn lined with a cheesy type of exudate. We were not able to demonstrate any microorganisms on smears. There was no suggestion histologically of acute tuberculosis anywhere in the body. I think that the origin of the cavity was unquestionably a tuberculous empyema. The recent cavitation, however, was probably a mechanical phenomenon associated with blocking of the lymphatic channels and the accumulation of chylous material.

DR. KING So the "thick turbid fluid" was one place where I went astray. I assumed that it was purulent, but I was not told that it was purulent.

DR. MALLORY I did not see the fluid removed by thoracentesis. It is possible that it was purulent, but I suspect that it was similar to that which we saw a few weeks later at autopsy, which was definitely not purulent.

DR. KING Have you often seen cancer involving the thoracic duct?

DR. MALLORY No, it is apparently an unusual phenomenon. It is much commoner of course to see thoracic-duct occlusion from lymphomatous tumors.

DR. KING This was not cancer over the surface of the lung.

DR. MALLORY No, extensive cancer was present within the lung, especially in the lymphatic vessels. The right lower lobe — the one that appeared collapsed — was almost filled with carcinoma. In that lobe the cancer had invaded the bronchus. The gross picture of that area was not incompatible with primary cancer of the lung, but the rest of the pathological picture and the history ruled that out.

#### CASE 34032

##### PRESENTATION OF CASE

**First admission.** A twenty-one-year-old cook was admitted to the hospital because of cough, dyspnea and hoarseness.

Four months previously he developed a steady aching remitting pain that radiated to the shoulder and left arm and was unassociated with sensory or motor disturbances. It disappeared spontaneously about two months before entry, but he developed a deep chest cough, sometimes productive of white phlegm. The cough became more irritating, both day and night. In the last month he had progressive dyspnea on exertion and occasional night sweats. Two weeks before entry he developed persistent hoarseness and one week later noted intermittent pain in the right lower portion of the chest and some hemoptysis with the cough. The general condition remained good.

Physical examination revealed a well developed and well nourished man in no acute discomfort. He had obvious cough and hoarseness. The left leaf of the diaphragm was high and immobile, and in the base of the left lung the breath sounds were diminished, there were no rales. The trachea was in the midline. The superficial lymph nodes were not enlarged.

The temperature was 99°F, the pulse 90 to 100, and the respirations 20. The blood pressure was 138 systolic, 94 diastolic.

Examination of the blood disclosed a hemoglobin of 14.2 gm and a white-cell count of 15,000, with 84 per cent neutrophils. The blood nonprotein nitrogen, the total protein and a urine examination were within normal limits.

An x-ray film of the chest revealed an irregularly ovoid, soft-tissue mass in the anterior mediastinum,

which could not be definitely separated from the heart shadow. The mass projected more to the left, where its border was poorly defined. Areas of increased density radiated from the mass into the lung. The left leaf of the diaphragm was elevated and showed limitation of movement. The left pleural cavity contained a small amount of fluid. There was a mediastinal shift to the left on inspiration.

Bronchoscopy showed paralysis of the left vocal cord in abduction. The epiglottis was normal. The trachea was pushed to the right by an intrinsic mass on the left. The caliber of the trachea and the mucosa were essentially normal. The carina was pushed a little to the right, and was slightly widened and partially fixed. The right bronchial tree was normal. The left bronchial tree could be examined only for a distance of 3 cm beyond the carina because of fixation both laterally and medially.

An aspiration biopsy of the left side of the chest parasternally showed a few tumor cells considered to be carcinoma, but the biopsy was inadequate to warrant a definite diagnosis.

The patient was treated with 7200 r of x-ray therapy to the chest. The tumor regressed readily, and he was discharged.

*Final admission* (four months later). He was readmitted because of pain in the lower back radiating down the left leg to the ankle, which he had developed shortly after discharge from the hospital. He was given 1500 r of x-ray therapy to the lower spine, with questionable relief. Three weeks before entry he began to have weakness and numbness of the left leg, and two weeks later he began to have pruritus, most marked over the lower limbs. He lost about 10 pounds of weight in one month.

Physical examination revealed a well nourished man, with slight shortness of breath and hoarseness. The trachea was shifted to the left, and the breath sounds on the left were diminished. The left pupil was smaller than the right, and there was slight weakness of the left leg.

The white-cell count was 9100, with 83 per cent neutrophils. The urine showed a + test for albumin and had a specific gravity of 1.006. An x-ray film of the lumbar spine and pelvis demonstrated areas of rarefaction in the left ilium and pubic bones. In the chest there was enlargement and coalescence of the perihilar lymph nodes bilaterally, and marked elevation of the left leaf of the diaphragm.

The patient was treated with 3600 r of x-ray therapy to the pelvis and 1800 r to the chest. He vomited persistently and had a generalized Jacksonian seizure. He deteriorated progressively and died five weeks after admission.

#### DIFFERENTIAL DIAGNOSIS

DR. LOWREY F. DAVENPORT. We are given the salient facts in this case. A malignant tumor was discovered in the anterior mediastinum and hilar lymph nodes of the chest, causing severe localized

pressure symptoms. Subsequently, it metastasized to distant parts of the body, leading ultimately to death within a period of less than a year. Our chief concern, then, is the nature of this tumor. Apparently, a presumptive diagnosis of carcinoma was accepted on the basis of the cellular findings in the chest fluid. These findings were admittedly insufficient to warrant a final diagnosis and were accepted as a working diagnosis for therapy. It may be well to review the data in chronologic order to see if a more acceptable differentiation can be made.

This twenty-one-year-old man had initial symptoms of pain in the left shoulder and arm. Two months prior to the first admission he developed a cough, followed later by dyspnea and occasional night sweats. By the time he was admitted there was hoarseness, which was due to paralysis of the left vocal cord. So far these symptoms are more consistent with a malignant lymphoma than with a primary bronchiogenic cancer. The malignant lymphomas involve hilar lymph nodes early and frequently cause early pressure symptoms. At the age of twenty-one this type of tumor is certainly more common than bronchiogenic cancer, intermittent and hectic fever is frequently associated with lymphoma, particularly of the Hodgkin type. However, we are told that the patient had had some hemoptysis just prior to admission. As a general rule lymphoma does not cause bleeding, and in contrast to bronchiogenic cancer it does not originate in the bronchial mucosa and rarely invades it. I know of no single case in which a sufficient amount of lymphomatous tissue has been obtained by bronchoscopy to make a definite diagnosis. The occurrence of hemoptysis, then, is more commonly associated with carcinoma than with lymphoma.

The physical findings give no help in the differential diagnosis at the time of the first admission. There was definite paralysis of the left vocal cord and left side of the diaphragm, which only substantiates the previous impression of a malignant tumor. The absence of enlarged superficial lymph nodes is of no diagnostic importance. We know that extensive lymphoma can occur without such adenopathy, but had it been present it would definitely be against the diagnosis of bronchiogenic cancer.

The bronchoscopic examination showed fixation of the left bronchial tree, but no intrinsic tumor was discovered. We have come to associate such fixation with malignant involvement of the mediastinal structures, but in the absence of a positive biopsy we can go no farther in differentiating various types of malignant processes.

The laboratory data, with the exception of the findings following aspiration biopsy, are of no help. Actually, in this clinic, we have had little experience in recent years with aspiration biopsy. In contrast to other clinics, it has been our usual procedure to advise exploratory thoracotomy rather than attempt

aspiration biopsy. This course has been followed because of the very same difficulty with aspiration biopsy that was encountered in this case. All too frequently insufficient tissue is obtained for diagnosis. There is also the real danger of spreading a malignant process that might otherwise be operable. In spite of this very definite lead — that "tumor cells considered to be carcinoma" were discovered — I am not yet willing to accept this statement at its face value. For the purpose of therapy, I should have agreed to large doses of x-ray radiation, believing that it was better to overtreat a lymphoma than to undertreat a cancer.

We can exclude a primary tumor elsewhere involving the chest secondarily since all the information points toward a malignant tumor originating in the chest. Among malignant tumors in the anterior mediastinum carcinomas of the thyroid gland and thymus are possibilities, but the location of this tumor was too low for these organs to be considered as sites of origin. The patient's age, the location of the tumor and the x-ray findings are against a diagnosis of bronchiogenic cancer. If we accept the aspiration biopsy as showing cancer cells, which could not be identified, we should consider a teratoma or malignant degeneration in a dermoid cyst as possibilities. Both such tumors occur commonly in the anterior mediastinum and can show a varying degree of malignancy.

However, a malignant lymphoma would best fit the entire clinical picture. This was a malignant tumor in a man of twenty-one, at which age a lymphoma is certainly the most common type of tumor. The early involvement of the hilar nodes, the initial symptoms of an irregular and unexplained fever and the widespread metastases are consistent with this diagnosis. When confronted by a single laboratory finding that does not fit the rest of the clinical picture, it is usually a safe rule to disregard it. This is even more valid when the test was admittedly "inadequate." At best our experience with aspiration biopsy has been so unsatisfactory that I should disregard this single finding and make a diagnosis of malignant lymphoma involving primarily the mediastinal lymph nodes, with widespread metastases elsewhere.

DR MILFORD D SCHULZ. Films of the chest made at the first admission show a mass presenting in the left upper mediastinum, continuous with the lung root, which cannot be separated from the vascular shadows. It has an irregular ragged margin, and in the periphery of the lung, there is a homogeneous area of increased density. The left leaf of the diaphragm is elevated. A tumor mass arising in the mediastinum or in the left lung root causing paralysis of the left phrenic nerve and some patchy areas of atelectasis in the lung would look like this.

Films made after x-ray therapy show some regression of the mediastinal mass but no return of the diaphragm to normal position. Still later films of the chest demonstrate probable enlarged lymph

nodes at the right lung root. A film of the pelvis made at the same time shows mottled areas of bone destruction involving the left ilium and pubis.

These findings are consistent with involvement by some malignant process. Bones involved by lymphoma look like this.

DR DAVENPORT. In spite of the aspiration biopsy suggesting that the process was a carcinoma, is it not true that the type of involvement in the bones of the pelvis is unusual with carcinoma and is much more consistent with lymphoma?

DR SCHULZ. Metastatic carcinoma of the bone can have almost any appearance, but in view of the patient's age, I should consider some type of lymphoma a very likely cause for this type of destruction. The appearance is consistent with that seen in lymphoma or reticulum-cell sarcoma.

#### CLINICAL DIAGNOSIS

Carcinoma of mediastinum

#### DR DAVENPORT'S DIAGNOSIS

Malignant lymphoma of mediastinal lymph nodes, with widespread metastases

#### ANATOMICAL DIAGNOSIS

*Malignant lymphoma, reticulum-cell sarcoma type, involving mediastinal and other lymph nodes, kidneys, adrenal glands, lungs, intestine, stomach, thyroid gland and bones*

#### PATHOLOGICAL DISCUSSION

DR BENJAMIN CASTLEMAN. At post-mortem examination the mediastinum was a mass of fairly dense fibrous tissue in which could be found necrotic foci, apparently the remains of neoplastic lymph nodes. The x-ray treatment had really been effective, because the microscopical sections of most of the lymph nodes in this region showed no viable tumor.

Dr Davenport's prediction of widespread involvement was certainly borne out. The most striking finding was a pair of kidneys with a combined weight of 2300 gm — about six times the normal weight. They were enormous and were diffusely infiltrated with tumor, not as metastatic nodules such as one sees in carcinoma, but a generalized infiltration of the interstitial tissues deflecting and crowding out rather than destroying tubules and glomeruli. This accounts for the absence of renal failure. Similar infiltration had occurred in the lungs, adrenal and thyroid glands, stomach, small intestine and pancreas, as well as in many lymph nodes.

Morphologically, the tumor belongs to the malignant lymphoma group, and can be subclassified as a reticulum-cell sarcoma. The latter type of malignant lymphoma has a predilection for involving viscera either alone or in addition to lymph nodes and quite often misses the spleen, as was true in this case.

## WATERS DEFILED

THE London *Lancet*,\* in a recent leading article, draws attention to the gross pollution of rivers and tidal reaches that exists today in Great Britain, practically unchecked. At Tynemouth, for example, the towns of Newcastle and Gateshead discharge each day approximately 30,000,000 gallons of untreated sewage into the tidal waters of the estuary—a mass of filth that requires several tides to clear away. The coastline of 150 miles between Liverpool and Barrow is the daily recipient of 200,000 gallons of crude sewage per mile, or about forty bucketsful per yard. In these waters people bathe by the thousands in hot weather, and from them shrimps and prawns are harvested for the nation's tables.

Interestingly enough, it is the British angler who is making the greatest outcry over this situation, for his salmon are disappearing, but Parliament will shortly have an opportunity to take cognizance of the situation when it considers the Rivers Boards Bill containing the recommendations of the Central Advisory Water Committee.

We have no superiority in this respect in our own country about which to brag, for we, too, have contaminated our streams and polluted our beaches without regard to health, decency or esthetic considerations. Harold L. Ickes in his column in *The Boston Traveler* of September 25, 1946, presents some figures that give an account of our stewardship over this land that spreads from sea to shining sea.

"More than 3400 cities and towns," he writes, "inhabited by 29,000,000 persons discharge into our waterways a volume of  $2\frac{1}{2}$  billion gallons of raw sewage plus  $3\frac{3}{4}$  billion gallons of industrial waste each day. The annual economic loss resulting from water pollution has been variously estimated at from a hundred million to a billion dollars."

Massachusetts made at least a start in the control of water pollution in 1945, when the Legislature authorized the Department of Public Health to prescribe rules and regulations "to prevent pollution of lakes, ponds, streams, tidal waters and flats and tributaries thereto." In certain instances it has been necessary to prosecute recalcitrant offenders before health hazards could be prevented and nuisances abated. In others, industrial wastes had become so obnoxious that living conditions in the vicinity were unbearable, and even the paint on buildings was discolored by gases containing hydrogen sulfide.

In 1947 further remedial measures were taken with the passing of legislation in Massachusetts, Connecticut and Rhode Island authorizing the ratification of a proposed compact between these states and the other New England states for the abatement of existing pollution and the control of future pollution in interstate waters. Putting these measures into execution will be slow, however, because of the costs involved and the scarcity of labor and materials for the construction of treatment works.

## VOIUNTARY HEALTH AGENCIES AND THE NATIONAL HEALTH COUNCIL

THE need for co-ordination and co-operation among voluntary health agencies particularly at the community level, has long been recognized. A cogent statement of proposals for greater efficiency that also contains an analysis of the problems and opportunities inherent in this phase of public health<sup>1</sup> was recently adopted by the National Health Council as a guide in the future development of its activities. If properly carried out any program based on the principles advocated in this memorandum should go far toward lightening the burden of illness, accident and premature death and, incidentally, toward eliminating the ever-present bugbear of governmental interference in medicine and public health. Proposals directed toward the attainment of such a goal merit the careful attention of all members of the medical profession.

The essential features of a local health council are defined as follows: representation of all operating health agencies in the community, both official and voluntary, continuous opportunity to study health needs and to assess health problems and work together on their solution, and an atmosphere of co-operation and tolerance for all members. The unified support of all voluntary agencies combined in a council is held to offer a great advantage to local health departments.

Existing health agencies struggling with identical problems will welcome advice (but not dictation) from a national source that is familiar with successful public-health methods throughout the country. Therefore, the closest co-operation of function among all health organizations is urged, but the idea of interfering with methods of fund raising or merging the functions of various agencies at the national level is rejected. The role of the National Health Council in this scheme for more efficient operation is regarded as vital, and it is recommended that the Council, which already comprises representation of such major organizations as the National Tuberculosis Association, American Red Cross, American Cancer Society, American Public Health Association and National Organization for Public Health Nursing,<sup>2</sup> be expanded to include

the Health Section of the Office of Education, the National Foundation for Infantile Paralysis, the American Medical Association (formerly a member), the American Hospital Association and other professional groups. Other recommendations include the establishment and expansion of a central statistical service and provision for a library and information service, since the National Health Council is not only in an advantageous position to observe and evaluate reports from all parts of the country and to suggest promising directions for further investigation but also especially fitted to stimulate sociologic and administrative research, which has lagged behind the more basic scientific investigations.

The specific proposals are based on the conviction that permanent progress in public health can best be achieved if people are helped to recognize and to solve their own health problems. The cordial attitude of the public toward health guidance and health agencies, the existence of more numerous and more competent bodies of health workers than ever before and the advantage of modern technique and scientific advances are considered to offer an unprecedented opportunity for constructive efforts to attain the goal of optimum health for the greatest number of people. The guiding principles proposed for the staff of the National Health Council are as follows: "field work, counselling and co-operation within and without, decentralization at every opportunity, focusing on problems, not on personalities, receptiveness to new ideas and to local viewpoints, suggestion rather than oracularity, a viewpoint broad enough to encompass the special interests of all health agencies, both voluntary and official, realization that many local health agencies are doing superior work and can contribute much to the national agencies."

Dr W P Shepard, author of these proposals and president of the National Tuberculosis Association, deserves the highest praise for a clear and constructive outline of public-health needs. The recommendations, essentially, apply the principle of the Community Fund to all matters pertaining to health. The progress of the National Health Council in forwarding the implementation of these suggestions will be closely watched by physicians and laymen alike, for the stake involved — maintain-

nance and improvement of health by democratic means — is vital

#### "THAT THESE HONORED DEAD"

A FUNERAL procession has begun this year that will consume five more before its ending Coming from the four quarters of the globe its various elements are converging on their homeland bearing the bodies of our dead of World War II

Congress has voted this posthumous repatriation and reburial, and the next of kin must make the decision whether to leave the body of the deceased where it was buried by his comrades or to bring it home for reinterment The soldier or the sailor cannot be consulted He has made his last decision on all matters earthly

The *Journal* published on November 13, 1947, a directive from the Department of Public Health regarding the technicalities of reburial in the Commonwealth, giving grim substance to this sentimental journey, and the relatives of more than 200,000 servicemen who lie buried in foreign soil have signified their desire to have the bodies returned There are those who feel that the deceased would wish to remain where he now is, others prefer that their relative shall rest in the homeland and this, too, is entirely fitting and proper

There may be many reasons given either for exhuming these unembalmed bodies and bringing them home for reburial or for leaving them in permanent United States military cemeteries abroad The ultimate reason is one of sentiment, whether the body shall lie in a grave that can be watched and tended by those of his own blood or rest in a bit of American soil in some other country — a sentiment once so fittingly expressed in the familiar words of Rupert Brooke "That there's some corner of a foreign field that is forever England"

However we may feel in this respect, there comes the thought that wherever "these honored dead" may lie, it is "for us, the living" still to show that "increased devotion to the cause for which they gave their last full measure of devotion"

Wherever they may lie, may we be stimulated to greater efforts to see that out of the destruction of war there shall come something better for those now living!

---

#### THE NEW ENGLAND DENTAL JOURNAL

The *New England Journal of Medicine* welcomes into the ranks of scientific journalism the *New England Dental Journal*, as the official publication of the six New England dental societies

The *New England Dental Journal*, a logical successor to the *Massachusetts Dental Society Bulletin*, which has been in publication since 1924, is making its bow with the new year Its publication will be in the hands of a representative committee composed of an editor from each New England state, under the two-year chairmanship of Dr Cedric F Haring, of Brookline, Massachusetts Dr Haring has been editor of the *Massachusetts Dental Society Bulletin* since January, 1945

---

#### MASSACHUSETTS MEDICAL SOCIETY

##### DEATHS

BAILEY — Karl R Bailey, M D, of Jamaica Plain, died on December 21 He was in his sixty-first year

Dr Bailey received his degree from Tufts College Medical School in 1910 He was deputy health commissioner for the City of Boston and was a former member of the Massachusetts Medical Society

His widow and two daughters survive

McDONALD — Ray T McDonald, M D, of Medford, died on December 5 He was in his sixty-second year

Dr McDonald received his degree from Tufts College Medical School in 1918 He was senior medical officer at the Lawrence Memorial Hospital, Medford, and a fellow of the American Medical Association

His widow, a son, a daughter and a brother survive.

MacGRAY — Charles L MacGray, M D, of Needham, died on December 25 He was in his sixty-eighth year

Dr MacGray received his degree from Tufts College Medical School in 1914 He was a member of the New England Pediatric Society and a fellow of the American Medical Association

His widow, a son, five daughters, two brothers and six sisters survive

PHILLIPS — Charles H Phillips, M D, of Beverly, died on December 22 He was in his seventy-seventh year

Dr Phillips received his degree from Bowdoin Medical School in 1900 He was formerly assistant medical examiner for Essex County and was a fellow of the American Medical Association

His widow, two daughters and three grandchildren survive

PICKARD — Isaiah L Pickard, M D, of West Concord, died on August 12 He was in his eighty-first year

Dr Pickard received his degree from Harvard Medical School in 1896 He was a former member of the Massachusetts Medical Society

# MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

## SCHEDULING IMMUNIZATIONS

So many considerations enter into determining the order and the age for the administration of immunizations that there is as yet no general agreement regarding an ideal plan.

The present recommendations of the Department concerning such schedules are given in Table I

Hospital, Harvard Medical School and Harvard School of Public Health

The unit is under the direction of Dr. Merrill C. Sosman, radiologist at the Peter Bent Brigham Hospital. Other personnel and equipment are provided by the Massachusetts Department of Public Health through grants from the Tuberculosis Control Division of the United States Public Health Service.

Through the use of 70-mm photofluorographic equipment, the cost of operation has been reduced

TABLE I Immunization Procedure Recommended

DISEASE	AGE AT TIME OF INITIAL DOSE	PRODUCT (ANTIGEN)	DOSE	INTERVAL BETWEEN DOSES	BOOSTER DOSE OR REIMMUNIZATION	REMARKS
Whooping cough	3-6	Pertussis vaccine	Three doses of plai vaccine (80,000,000,000 bacilli) alum precipitated vaccine (30,000,000,000 bacilli)	30	One dose 1 yr. later; repeated at 5-6 yr. plai vaccine (20,000,000,000 bacilli); alum precipitated vaccine (10,000,000,000 bacilli)	Vaccine may be combined with diphtheria toxoid; booster doses should be given when disease is prevalent.
Smallpox	3-6	Smallpox vaccine	One vaccination	—	At 5-6 yr. of age; every 5-10 yr. thereafter	Vaccine may be combined with any dose of pertussis vaccine; revaccination indicated when disease is prevalent.
Diphtheria	6-9	Diphtheria toxoid*	Three doses of 0.5 cc. and 1.0 cc.	21-30	One dose (0.5 cc.) at 3-6 yr. of age†	Booster doses should be given at shorter intervals when diphtheria is prevalent.
Tetanus	6-12	Tetanus toxoid	Two doses of 1.0 cc. each	30	Recall dose (1.0 cc.) 1 yr. later	Another dose indicated after each deep or contaminated wound.
Typhoid fever	(When advised by physician)	Typhoid vaccine	Three doses of 0.5 cc. and 1.0 cc.‡	7-10	One dose (0.5 cc.) annually in areas where needed†	Triple vaccine should be given to travelers.

\*Two doses, 30 days apart, should be used for alum-precipitated toxoid.

†For booster dose, 0.1 cc. intracutaneously can be used.

‡Three doses of 0.5 cc. each recommended by some.

§For adolescents and adults, the first dose of diphtheria toxoid should be 0.1 cc., the size of succeeding doses being gauged by the reaction from the first inoculation.

These recommendations will be amended as new knowledge on many points is brought forward.

If every family followed a schedule of this kind, these diseases would become of little importance in Massachusetts.

Because parents often neglect to have the immunizations done by their own physicians, boards of health have been compelled to organize community immunization programs. In such programs, departure from the recommended procedures must occasionally be made. The essentials, however, can easily be covered in these programs.

## HARVARD PUBLIC HEALTH CHEST CLINIC

The official opening on Friday, November 7, of the Harvard Public Health Chest Clinic, located in the former Huntington Memorial Hospital, now part of the Harvard School of Public Health, marked a new step in co-operative tuberculosis prevention. By pooling funds, equipment and personnel, the Harvard Public Health Chest Clinic was brought into existence to serve the Peter Bent Brigham Hospital, Boston Lying-In Hospital, Children's

to the extent that the project is economically feasible.

The objective is to provide routine x-ray examinations of patients and employees of the member hospitals, as well as students and employees of Harvard Medical School and Harvard School of Public Health.

Since it has been shown that the tuberculosis rate of patients in general hospitals is approximately twice that of persons in the ordinary population, it is hoped that the routine screening for tuberculosis as proposed in this program will prove an effective means of disclosing unrecognized cases and protecting the hospital employees, medical-school personnel and nurses.

## MISCELLANY

### NOTES

The following appointments to the teaching staff of Harvard Medical School were recently announced: René Tagnon of Brussels, Belgium (A.B. University of Brussels 1939, M.D. University of Liège Medical School 1943), research fellow in medicine; Albert Kam Tai Ho, of Honolulu, Hawaii (S.B. University of Hawaii 1937, M.D. Jefferson Medical

College 1942), assistant in laryngology, Raymond Frank Kuhlmann, of Milwaukee, Wisconsin (A B University of Wisconsin 1936, M D Washington University 1939), assistant in orthopedic surgery, Herbert Fanger of Brookline (A B Harvard University 1936, M D New York Medical College 1940), assistant in pathology, Arthur Burns of Brighton (S B Boston College 1922, M D Tufts College Medical School 1926), teaching fellow in radiology, Chun-Hsiang Liu, of Peiping, China (M B Ministry of Education, China, 1940, M D National Tung-Chi University Medical School Shanghai 1941, D T M Calcutta School of Tropical Medicine 1945), research fellow in physical chemistry, Robert Fernand Mouton, of Brussels, Belgium (S D Brussels Free University 1944), research fellow in physical chemistry, Hans Nitschmann, of Berne, Switzerland (Ph D University of Berne 1931), (Privatdozent University of Berne 1942), research fellow in physical chemistry, Charles Tanford, of Boston (A B New York University 1943, A M Princeton University 1944, Ph D Princeton University 1947), research fellow in physical chemistry, Eero Johannes Uroma, of Helsinki, Finland (M D University of Helsinki 1943, Privatdozent Sero-Bacteriologie, Helsinki, 1947), research fellow in physical chemistry, Luis Saenz-Arroyo, of Mexico, D F (S B Institut Franco-Anglais 1937, M D National University of Mexico D F), research fellow in neurology, Lloyd Irving Sexton, of West Newton (S B Tufts College 1939, M D Boston University School of Medicine 1943), research fellow in obstetrics, Harry Amerman Bliss of Buffalo, New York (A B Princeton University 1941, M D Harvard University 1944), research fellow in physiology, John Lu, of Nanking, China (V Sc West China Union University 1940, M D West China Union University 1945), research fellow in surgery, John Eric Richardson, of Leicestershire, England (M B London Hospital Medical College 1939, M S London Hospital Medical College 1941, F R C S London Hospital Medical College 1944), research fellow in surgery, Joseph Worcester Spelman, of Kent, Connecticut (M D Yale University 1944), research fellow in legal medicine, John William Raker, of Boston (S B Bucknell University 1937, M D Harvard University 1941), research fellow in biologic chemistry, and Ian Chester Jones, of Liverpool, England (B Sc Liverpool University 1938, Ph D University of Liverpool 1941), research fellow in dental science.

#### NATIONAL CANCER INSTITUTE OF THE UNITED STATES PUBLIC HEALTH SERVICE

Awards totaling nearly \$750,000 in National Cancer Institute grants have been announced in a report made public by Dr. Thomas Parran, Surgeon General of the United States Public Health Service. Altogether 46 grants for clinical and basic biologic research were given on the recommendation of the National Advisory Cancer Council, composed of outstanding authorities on cancer from various sections of the country.

For the first time in the ten-year history of the Council grants were given to scientists working outside this country. The two recipients were Dr. A. Lacassagne, of the Institute Pasteur in Paris, who received \$13,380, and Dr. L. Doljanski, of Hebrew University in Palestine, who received \$10,000.

#### AMERICAN COLLEGE OF PHYSICIANS RESEARCH FELLOWSHIPS IN MEDICINE

Research fellowships in medicine, with stipends ranging from \$2200 to \$3200, have been awarded by the American College of Physicians to the following physicians, for the year beginning in July: Charles G. Campbell, of Vancouver, B. C., for studies of the basic physiology of certain cardiovascular problems (at McGill University Faculty of Medicine), Frank H. Gardner, of San Bernardino, California, for studies of the mechanism and clinical application of the osmotic fragility test (at the Thorndike Memorial Laboratory, Boston City Hospital), Samuel P. Martin, of Durham, North Carolina, for studies of bacterial metabolism (at the Rockefeller Institute for Medical Research, New York City), Peritz Scheinberg, of Miami, Florida, for studies of cerebral circulation and peripheral vascular flow in normal and hypertensive per-

sons (at Duke University Hospital), Lutfu Lahut Uzman, of Istanbul, Turkey, for studies of the isolation and characterization of brain proteins and their role in health, disease and senescence (at the Department of Scientific Research, McLean Hospital, Waverley, Massachusetts), and John M. Weller, of Ann Arbor, Michigan, for studies of the ionic patterns of intracellular fluids and their influence on enzymatic reactions and of acid-base balance in tissues other than skeletal muscle tissues (at the Department of Biologic Chemistry, Harvard Medical School).

#### INDUSTRIAL CONFERENCE ON ALCOHOLISM

The first Industrial Conference on Alcoholism will be held in the Morrison Hotel, Chicago, on Monday, March 15. Sponsored by the Chicago Committee on Alcoholism, the Conference has been designed to bring to the attention of industrial leaders throughout the country facts pertaining to the problem of alcoholic employees and to discuss ways and means of overcoming the problem.

The Conference has been divided into three parts. In the morning session the discussion will center around "The Problem."

The second session will be held at a special luncheon at which an outstanding authority on the subject will be the key speaker. The afternoon session will cover the subject "What To Do about the Problem."

Reservations for attending the technical sessions and the luncheon may be made by application in writing to Walter O. Cromwell, vice-president, Chicago Committee on Alcoholism, 816 South Halsted Street, Chicago 7, Illinois.

#### "THIS WEEK IN CHICAGO MEDICINE"

The Chicago Medical Society has inaugurated a weekly mimeographed publication entitled "This Week in Chicago Medicine," designed to keep the medical profession posted and to aid out-of-town physicians who wish to visit clinics, conferences, round tables or medical meetings in Chicago.

Any doctor planning a trip to Chicago may obtain copies of this bulletin by writing to the Chicago Medical Society, 30 North Michigan Avenue, Chicago 2, or by calling in person.

#### BOOK REVIEWS

*Hypnotism Today*. By Leslie M. Lecron, B. A., and Jean Bordeaux, M. A., Ph. D. With a foreword by Milton H. Erickson, M. D. 8°, cloth, 278 pp. New York: Grune and Stratton, 1947. \$4.00.

The expressed purpose of this book is to "demonstrate that hypnotism is a true branch of psychological science, and to aid in removing some of the last lingering traces of the esoteric which still cling to it." So far as the authors adhere to the topic of hypnosis they do well in presenting the historical background and in offering critiques of existent laboratory studies, but these critiques are for the most part empirical and subjective. However, the authors digress at great length, with frequent interjections from their own experiences, into summary descriptions of behavior abnormalities (nonpsychotic), depiction of systems of psychotherapy in present vogue and further ramifications into the emotionally fraught question, "In whose bailiwick lies psychotherapy? They make out a plausible case for hypnosis ancillary to psychoanalysis (nonorthodox).

In many respects this volume has merit in its suggestions for measuring depth of the hypnotic state, in pointing out various weaknesses in past studies and present application and in offering leads for future research. The excursions across other horizons create a fog through which the title subject looms only occasionally. The authors in their zeal become somewhat evangelical and lose effectiveness through this disunity. The book ends with observations and philosophical conjecturing on the present training of physicians (psychiatrists) and psychologists (clinical psychologists) and equivocating about definitions of psychotherapy and treatment.

The book is easily read, and when the authors adhere to the title they present suggestions from their empirical experience that may be of value in stimulating objective work with hypnosis. The volume contains one hundred and twenty-six references and an index.

*Diseases of the Chest. Diagnosis and treatment.* By Archibald R. Judd M.A., M.D. 8°, cloth 608 pp., with 140 illustrations. Philadelphia F A Davis Company, 1947 \$9.00

In his preface the author outlines the objective of this book as a concise, practical and systematic manual of diseases of the chest. He emphasizes the fact that he wrote it to fill the needs of the general practitioner, intern or medical student and not for the specialist. It is with this in mind that the reviewer has gone over the twenty seven chapters of this manual.

There are five parts that consider the anatomy and physiology of the thorax, a fairly exhaustive study of pulmonary tuberculosis, nontuberculous pulmonary suppurative diseases of the lungs and pleura as well as silicosis, neoplasms, fungous diseases and cystic disease and finally miscellaneous aids in diagnosis, including bronchoscopy, bronchography and various other laboratory aids.

The author has long been a recognized authority on diseases of the chest and has absorbed much of the enthusiasm and zeal in the study of bronchology and pulmonary diseases from his close associates, the Jacksons. As a result of this major interest of the Philadelphia group there has certainly evolved, in the past quarter of a century, a much better and clearer concept of the physiology, pathology and rational treatment of lung diseases. The author discusses the subject quite adequately with an excellent interpretation of the long background and his personal experience in lung diseases.

Unfortunately, books do not have a morning and evening edition. In this atomic age there is nothing more perishable than a book on practical treatment. Some of the procedures are outmoded before the book reaches the shelves of the bookstore. Thus the omission of streptomycin to the general scheme of therapy in pulmonary tuberculosis is bound to leave quite a vacuum. Undoubtedly streptomycin is here to stay, and the entire early treatment especially that of tracheobronchial tuberculosis and other tuberculous complications will have to be reconsidered. In the light of present knowledge the entire chapter on tuberculous bronchitis will have to be rewritten immediately.

Likewise the chapter on carcinoma of the lungs lacks the latest procedures of bronchoscopic aspirations and the newer staining methods which make early diagnosis possible in a much higher percentage of cases.

The place of lobectomy and pneumonectomy in pulmonary tuberculosis is much more clearly defined now in view of the newer armamentariums on the treatment of pulmonary diseases. The remarks presented above are not meant as a criticism of the book but point to the need of a new edition almost before the ink has had a chance to dry.

Aside from the few omissions outlined, the author has covered the ground of all chronic diseases of the chest in a very adequate and practical manner. The general practitioner will find it an excellent reference book and the medical student will find it very useful as a condensed manual of all chest diseases. It is certainly a welcome addition to the literature on diseases of the chest.

*Signs and Symptoms. Their clinical interpretation.* Edited by Cyril M. MacBryde, M.D. 4°, cloth 439 pp., with 74 illustrations and 6 plates. Philadelphia J B Lippincott Company, 1947 \$12.00

The title of this unusually well organized composite work defines clearly the objective of the authors—namely to impress the physician with the importance of understanding correctly the complaints for which the patient consults him. With such an understanding a careful clinical history not only will simplify the physical examination and the selection of specialized laboratory tests but also will determine in large measure the correct diagnosis and appropriate treatment.

After an introduction by the editor on the art of history taking and on the technique of interpreting symptoms there follow twenty six sections or chapters covering nearly the entire field of symptomatology. Because pain is by far the most common presenting symptom a third of the book is devoted to this subject in its various manifestations: head ache, sore tongue and mouth, thoracic, abdominal, back and joint pain and pain in the extremities. Next are taken up fever, fainting and convulsions, dyspnea, cyanosis, palpitation, cough and hemoptysis, edema and dehydration, anorexia, vomiting and hematemesis, constipation, diarrhea and melena, jaundice, itching and finally, nervousness and fatigue.

Because the list is so comprehensive it is surprising that symptoms such as vertigo, purpura and hematuria have not been included.

Each section is a finished monograph in itself, concise and well correlated with the rest. The mechanism of each major symptom is clarified by whatever bearing anatomy, pathology, physiology, chemistry or psychology may have on it, and its correlation with other symptoms and with physical and laboratory findings is emphasized. The text is illustrated with many charts, diagrams and photographs in black and white and in color. References follow each section. Local contributors are Sara M. Jordan and William G. Lennox.

All in all this comprehensive work fulfills well the objective of the authors to help the physician evaluate the signs and symptoms of disease so that he may reach a correct diagnosis.

*Concise Anatomy.* By Lindeu F. Edwards Ph.D. 4°, cloth 548 pp., with 324 illustrations. Philadelphia The Blakiston Company 1947 \$5.50

This book admirably fulfills its intention to teach the basic principles of human anatomy to students in fields ancillary to medicine, such as nursing and physical education. It supplants the previous text by the same author entitled *Anatomy for Physical Education*. Much new material has been added, and the author correlates the anatomy with physiology and other applied matters. Although it is concise and simply written, the volume is entirely scientific in its approach and is obviously directed to people at college level. The illustrations and format are both instructive and pleasing and the book can be heartily recommended for students in the fields mentioned above.

*Diseases of the Gallbladder and Allied Structures. Diagnosis and treatment.* By Moses Behrend, M.D. With a foreword by Thomas A. Shallow M.D. 8°, cloth 290 pp., with 110 illustrations. Philadelphia F A Davis Company, 1947 \$7.00

This book is a review of forty five years' experience in the medical and surgical management of diseases of the gall bladder, bile passages and pancreas.

In the chapter on interpretation of liver function tests the limitations of the tests and their optimal value during the course of jaundice and convalescence are not included. It is stated that the prothrombinogen in the urine is increased in hepatocellular jaundice. However in the reviewer's experience this urinary pigment may be present in low levels or absent during the acute hepatocellular jaundice and is increased amounts only at the onset or at convalescence of the disease, when bile pigment is present in large quantity in the intestine. This test is frequently not of much help during the height of the illness, because the severely damaged liver may not be capable of manufacturing bile pigments. Its outstanding value is in revealing the patency of the common bile duct.

The omission of the value of the simple hippuric acid test as an indication of dehydration in the preoperative preparation of the patient with cholecystitis was probably an oversight.

The statement that persistent hypoprothrombinemia in spite of adequate intramuscular administration of vitamin K is a differential point excluding obstructive jaundice in favor of acute hepatocellular jaundice is not valid. In a large series of both obstructive and acute hepatocellular cases the responses of hypoprothrombinemia to vitamin K were approximately the same. Persistent hypoprothrombinemia in spite of adequate vitamin K occurred in chronic parenchymatous hepatitis and was usually an unfavorable prognostic sign.

None of the function studies described have revealed liver damage in the presence of severe grades of congestive heart failure.

The potential danger of increased liver damage if sulfonamides are used in jaundiced patients is overrated. The low incidence of sulfonamide sensitivity makes the use of these drugs relatively innocuous.

Recommendation of the indiscriminate use of plasma in preoperative preparation without knowledge of the source of the plasma may well result in more cases of homologous serum hepatitis, some of which are fulminating.

Anatomic variations and recent operative procedures are very well illustrated. The diagnosis and treatment of cholecystitis and pancreatic diseases are well outlined.

## BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

*Twenty-Four-Hour Variations of Gastric Function and Their Significance for Diagnosis, Prophylaxis and Treatment of Dyspepsia, Especially in Tuberculosis*. By Erik Forsgren, M.D., physician-in-chief, Svenshögen County Sanatorium, 4°, paper, 34 pp. Lund, Sweden: Hakan Ohlssons Boktryckeri, 1946.

This study is based on routine examinations of 120 sanatorium patients, who were divided into two main groups: those with homoacidity and those with heteroacidity. They were studied on the basis of correlation between gastric acidity and subjective symptoms of dyspepsia and the correlation of tuberculosis and gastric function. The development of achylia and anemia associated with tuberculosis and the significance of the twenty-four-hour variation of gastric function from both the diagnostic and the hygienic viewpoints are discussed at length. A section is devoted to the treatment of achylia, especially in tuberculous subjects. The paper concludes with a summary in which the author states that he believes that routine examination of twenty-four-hour variations of gastric function should be made if there are symptoms of peptic ulcer, indigestion, deficiency conditions or tuberculosis.

*The Years After Fifty*. By Wingate M. Johnson, M.D., professor of clinical medicine and chief of private diagnostic clinic, Bowman Gray School of Medicine, Wake Forest College. With a foreword by Morris Fishbein, M.D. 8°, cloth, 153 pp. New York: McGraw-Hill Book Company, Incorporated, \$2.00.

During the past few years a number of popular books have been written on the hygiene and management of old age. Dr. Johnson has added another to this growing series and seemingly has not been able to reach down to the level of the layman but has landed in the middle between the physician and the subject. The style is factual and not conducive to easy interesting reading. The short comments are more on the professional than on the lay level.

*A Manual of Fractures and Dislocations*. By Barbara B. Stimson, M.D., M.Sc.D., assistant professor of clinical orthopedic surgery, College of Physicians and Surgeons, Columbia University, and associate attending surgeon, Presbyterian Hospital and Vanderbilt Clinic, New York City. Second edition. 12°, cloth, 223 pp., with 98 illustrations. Philadelphia: Lea and Febiger, 1947. \$3.25.

This manual has been revised in the light of war experience and has been brought up to date especially in the field of treatment. It should prove useful for ready reference to student and practitioner alike.

*Advances in Pediatrics*. Volume II. 8°, cloth, 409 pp., with 84 illustrations. New York: Interscience Publishers, Incorporated, 1947. \$6.75.

This second volume presents eleven special monographs on pediatric subjects of diversified interest and should prove valuable to the physician, as well as the pediatrician. The subjects discussed include the etiology of congenital malformations, endocrine and other factors determining the growth of children, prematurity, physiologic hyperbilirubinemia, the prevention of recurrences of rheumatic fever, acute infectious lymphocytosis, treatment of purulent meningitides, virus diarrhea, atypical pneumonia, the role of fluorine in prevention and treatment of dental caries and chemotherapy, including penicillin, the sulfonamides, streptomycin and tyrothricin. The papers are well written and provide up-to-date information on the various subjects. The book is well published in every way and should be in all medical libraries.

*Psychiatric Research*. Papers read at the dedication of the Laboratory for Biochemical Research, McLean Hospital, Waverley, Massachusetts, May 17, 1946. By Cecil K. Drinker, M.D., Sc.D., Jordi Folch, M.D., Stanley Cobb, M.D., Herbert S. Gasser, M.D., Sc.D., LL.D., Wilder Penfield, C.M.G., M.D., Sc.D., F.R.S., and Edward A. Strecker, M.D., Sc.D. 8°, cloth, 113 pp. Cambridge, Massachusetts: Harvard University Press, 1947. \$2.00. *Harvard University Monographs in Medicine and Public Health*, No. 9.

The seven papers comprising this volume are written by outstanding authorities in their particular fields. Dr. Drinker writes on research at the McLean Hospital, Dr. Folch on biochemical problems related to psychiatry, Dr. Stanley Cobb on the integration of medical and psychiatric problems, Dr. Gasser, director of the Rockefeller Institute, on a protocol for a review of psychiatry, Dr. Penfield, of McGill University, Montreal, on psychical seizures, and Dr. Strecker, of the University of Pennsylvania on the psychobiology of psychiatric research. This volume should be in all medical libraries and in all institutions having to do with mental disease. The small volume is published in the usual fine style of the Harvard University Press.

## NOTICES

## ANNOUNCEMENTS

Dr. Max Ettenberg announces the removal of his office to 258 Harvard Street, Cambridge.

Dr. Stanley J. G. Nowak announces the opening of his office for the practice of surgery at 99 Commonwealth Avenue, Boston.

## GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Tuesday, January 20, at 8:15 p.m. A symposium on "Recent Advances in Chemotherapy" will be presented. Dr. Chester S. Keefer will be chairman.

## PROGRAM

Treatment of Pneumonia and Meningitis, with Some Consideration of Modern Trends in Time-Dose Relations in Antibiotic Therapy. Dr. Maxwell Finland.

Antibiotic Therapy in Scarlet Fever and Diphtheria, with a Consideration of the Change in Bacterial Flora of Infections during and following Treatment. Dr. Louis Weinstein.

Role of Streptomycin in the Treatment of Urinary-Tract Infections, with a Consideration of Its Toxicity. Dr. William L. Hewitt.

## LOWELL LECTURES ON THE HOSPITAL IN CONTEMPORARY LIFE

The following lectures, which comprise the second half of a course of eight Lowell Lectures on the subject "The Hospital in Contemporary Life," will be given in the Lecture Hall, Boston Public Library, Copley Square, Boston, at 8 p.m. on the days indicated.

Tuesday, January 20. The Education of the Doctor. Dr. Oliver Cope.

Friday, January 23. How Medicine Grows and Its Relation to Science. Dr. Eugene M. Landis.

Tuesday, January 27. Unsolved Problems. Dr. Joseph C. Aub.

Friday, January 30. The Place of the Hospital in the Social Order. Dr. Nathaniel W. Faxon.

Tickets can be obtained by mail, in advance, from the Curator of the Lowell Institute, Boston Public Library, from the office of the Director, Massachusetts General Hospital, or at the door immediately before each lecture.

(Notices concluded on page viii)

# Only Way to "Handle" Poison Ivy

*Every now and then, Doc Hollister gets a serious case of poison ivy—like the time Ma Hoskins couldn't play the organ—and I run a notice in the paper, suggesting folks check up on their places for signs of the weed*

That's all that's necessary. Everybody makes a careful check, and usually it's just a single patch that needs uprooting. Because vigilance keeps poison ivy down, just the same way it controls everything else.

*Take our Better Business Bureau or the Brewers' Program of "Self Regulation." The Brewers are anxious to keep undesirables out of the "field," so they keep a constant check on taverns selling beer. If they see any signs of "poison ivy," the offending tavern gets cleaned up or reported to law enforcement agencies.*

Naturally, the tavern keepers are anxious to co-operate. And as a result any "poison ivy" is a rare exception. Because, as I say, vigilance is a mighty effective control.

# It Can Happen Here

*Example of severe rickets in a sunny clime.*

**L**EST WE FORGET—we who are of the vitamin D era—severe rickets is not yet eradicated, and moderate and mild rickets are still prevalent. Here is a white child, supposedly well fed, if judged by weight alone, a farm child apparently living out of doors a good deal. This boy was reared in a state having a latitude between 37° and 42°, where the average amount of fall and winter sunshine is *equal to that in the major portion of the United States*. And yet such stigmata of rickets as *genu varum* and the quadratic head are plain evidence that rickets does occur under these conditions.

How much more likely, then, that rickets will develop among city-bred children who live under a smokepall for a large part of each year. True, vitamin D is more or less routinely prescribed nowadays for infants. But is the antiricketic routinely administered in the home? Does the child refuse it? Is it given in some unstandardized form, purchased from a false sense of economy because the physician did not specify the kind?

A uniformly potent source of vitamin D such as Oleum Percomorphum, administered regularly in proper dosage, can do more than protect against the gross visible deformities of rickets. It may prevent hidden but nonetheless serious malformations of the chest and the pelvis and will aid in promoting good dentition. Because the dosage is measured in *drops*, Oleum Percomorphum is well taken and well tolerated by infants and growing children.

## OLEUM PERCOMORPHUM WITH OTHER FISH-LIVER OILS AND VIOSTEROL

Potency, 60,000 vitamin A units and 8,500 vitamin D units per gram. Supplied in 10 cc and 50 cc bottles, and as capsules in bottles containing 50 and 250

## MEDICAL AND HOSPITAL CARE OF THE VETERANS IN MASSACHUSETTS\*

WINTHROP ADAMS, M D †

BOSTON

THE entitlement of veterans to hospital and outpatient care under laws and regulations administered by the Veterans Administration is a part of any consideration of provisions for and distribution of medical care in Massachusetts, since there are approximately 600,000 veterans of wartime and peacetime service residing within the Commonwealth. All of these, comprising about 14 per cent of the entire population, are potential beneficiaries of these laws and regulations.

These veterans, men and women, who have served in the military forces are entitled, under existing federal laws, to medical care, including hospitalization or outpatient service for the relief of disabilities incurred in military service. There is further provision that, even though the disability was not incurred in the service, they are entitled to hospital care in Government hospitals for any disability requiring such care, regardless of when incurred, provided that they subscribe to a statement that they are unable to pay for the service elsewhere and provided that beds in Government hospitals are available.

Thus, veterans fall into two categories of entitlement to medical care: those with service-connected disabilities, and those with nonservice-connected disabilities. Of the 600,000 veterans in Massachusetts, approximately 79,000 have disabilities adjudged as service connected. It must be appreciated that many of these disabilities, such as amputations and loss of sight and hearing, as well as residua of wounds, are more or less static and permanent and will require little, if any, medical attention. However, pulmonary, cardiac and various other organic diseases, as well as nervous and mental afflictions, will require hospital or outpatient care for an indefinite period.

Of interest to the medical profession, as well as the public at large, is the plan of the federal Government, through the Veterans Administration, to provide

for the medical care of veterans in the Commonwealth.

At the present time, in Massachusetts, the Veterans Administration is operating five hospitals, with 4797 beds, 3100 of which are solely for the care of the mentally afflicted, 498 for tuberculosis, and the remainder—about 1200—for general medical and surgical cases. These hospitals are as follows: West Roxbury (general, 382 beds), Bedford (neuropsychiatric, 1822 beds, including 85 for women), Rutland 496 beds for tuberculosis, Framingham, formerly the United States Army Cushing General Hospital (general, neuropsychiatric and tuberculosis, 1000 beds)—this is one of the seven centers for paraplegic patients, includes 52 beds for women and is one of the Veterans Administration centers for the rehabilitation of aphasic and neurosurgical patients, and Northampton, 1095 beds for mental cases. In addition, the Veterans Administration has access to 250 beds in other Government hospitals, including the United States Naval Hospital at Chelsea and the United States Marine hospitals at Brighton and Vineyard Haven. As of a recent date, a total of 4724 veterans were hospitalized in Veterans Administration and other Government hospitals in the Commonwealth, 2091 of whom were receiving care for service-connected disabilities, and the remainder—more than half, or 2633 cases—for nonservice-connected ailments. Only 155 patients were hospitalized in civil or state hospitals.

The plans for the immediate future for additional hospital construction provide for a 1000-bed general medical and surgical hospital in Boston and a 1000-bed neuropsychiatric hospital near Boston. Upon completion, during 1950-1951, this will provide a total of about 6700 beds in Veterans Administration hospitals in Massachusetts, with the probability that further additional construction will be required before the estimated peak load is reached—between 1965 and 1970.

Outpatient service is an integral part of medical care for veterans. During a recent month, 9008 veterans received one or more physical examinations, and 12,990 were treated on an outpatient basis,

\*Part of a symposium on medical care presented at the annual meeting of the Massachusetts Medical Society, Boston, May 20, 1947.

†Branch medical director, Veterans Administration.

either in established Veterans Administration clinics or by physicians in the community in which the veterans reside

The Veterans Administration has established outpatient clinics in Boston, Worcester, Springfield, Lawrence, Lowell and New Bedford, with 46 full-time physicians and 42 part-time physicians employed. In the hospital service in Massachusetts, there are 70 full-time and 108 part-time physicians, including consultants and attendings, 71 residents and 66 young medical officers detailed from the Army and Navy, making a total of 315.

Although outpatient medical service to entitled veterans is practically restricted to state lines, no such limitation applies to hospital service. In other words, Massachusetts veterans receive outpatient treatment at clinics operated by the Veterans Administration or by civilian clinics or private physicians within the Commonwealth, but the Veterans Administration hospitals serve a veteran population in a general area. For instance, no construction of hospitals for the mentally afflicted or the tuberculous in Rhode Island, New Hampshire or Vermont is contemplated, consequently, beds in the neuropsychiatric hospitals in Massachusetts—at Bedford, Northampton and the proposed new center near Boston—will be available for the care of mentally afflicted veterans from other states.

Regarding the so-called "home-town care of veterans" an unfortunate situation arose, because of misleading publicity that appeared in press releases when this plan was started in certain states, as in Kansas, Michigan and New Jersey. It led many physicians, as well as the veterans themselves, to believe that family physicians could provide any sort of medical treatment, at Government expense. The releases did not stress the fact that the Veterans Administration could pay only for the treatment of service-connected disabilities and that, except in emergencies, the veterans should obtain prior authorization for the service required. Furthermore, it was not made clear that the Veterans Administration must use its established clinics to full capacity, and that veterans may be referred to private physicians only when reporting to the Veterans Administration clinic would work a hardship, such as loss of employment, or because of conditions prohibiting travel. The implementation of this plan in many sections, and this has been applicable to New England, has presented many difficulties, including agreement between the Veterans Administration and the state medical societies concerning a satisfactory fee schedule and the method of carrying the overhead—that is, whether or not an intermediary, such as the Blue Shield or Blue Cross, would serve as such an agent.

Negotiations between the Veterans Administration and officials of the Massachusetts Medical Society, through the Massachusetts Medical Services, Inc., have resulted in the adoption of a reasonably

satisfactory schedule of fees for various medical services. It was agreed that the Massachusetts Medical Service, Inc., would serve as the intermediary at a nominal charge for overhead, to be paid by the Veterans Association. Under this plan, the Massachusetts Medical Service, Inc., would receive initial authorization for the examination or treatment of a veteran, or a group of veterans, in a given community. The Massachusetts Medical Service would then advise the veteran, furnishing him with a list of physicians in his community who had expressed willingness to participate and serve. The veteran would go to the physician of his choice, who would submit his bill to the Massachusetts Medical Service for payment.

Authorization for treatment would carry authorization to prescribe indicated medication. The prescription would be presented to a local pharmacy for filling.

However, after the consummation of a contract with the Massachusetts Medical Service, Inc., it was found that the enabling act did not permit its negotiation with a federal agency, and amendatory legislation was requested. Such legislation has not to date been enacted, owing to objections on the part of certain groups.

Accordingly, unless favorable legislation is forthcoming, the implementation of this "home-town care plan" through the services of an intermediary, such as the Blue Shield or Blue Cross, will be impossible, and it will have to be worked out in accordance with the Kansas Plan, which comprehends direct action between the Veterans Administration and each individual physician who may be authorized to examine or treat a veteran.\*

There is, of course, no sound objection to this procedure, except that there will be a certain delay in effecting payments to physicians, owing to the paper work required in expending appropriated funds, under rather complicated procedures of Government accounting. With an intermediary functioning and willing to assume responsibility for direct payment to participating physicians, payment would be received more expeditiously.

Over the years, since World War I, the question has repeatedly been raised how far the federal Government should go in furnishing medical and hospital care to those who have served in the military forces. There has never been any question of the Government's obligation to those who became disabled as a direct result of their service, and I assume that no serious objection can be raised to governmental provision for the care of the mentally afflicted and tuberculous, regardless of the time of incurrence of the disability.

After World War I and until 1924, the statutes governing veterans' relief provided only for compensation and medical care for disabilities actually

\*Since this paper was delivered the Massachusetts Medical Society has entered into a new agreement with the Veterans Administration providing for the delivery of medical service according to the Kansas Plan.

incurred in service. If those statutes were in effect at this time, the Veterans Administration would be obligated to provide hospitalization for about 35,000 veterans instead of 104,000, the number hospitalized at the end of a recent month, and in Massachusetts, 2090 instead of 4724.

The service-connected cases hospitalized at that time comprised 6800 general medical and surgical, 6000 for tuberculosis and 22,000 classed as neuropsychiatric, the majority of which were psychotic patients. Of the nonservice-connected group under hospital care, about 68,000 in all, 32,000 were classed as general medical and surgical cases, 5800 as tuberculosis, and 31,000 as neuropsychiatric. These are national figures, but practically the same ratios prevail in the several areas throughout the country. Projected into the future, until 1965, when the peak load will be reached, a bed requirement of 225,600, including 7500 for tuberculosis, 121,200 for neuropsychiatric cases and 96,900 for general medical and surgical cases, is estimated. Of this total, probably not more than 35 per cent of the beds will be occupied by veterans with service-connected disabilities.

In the time allotted, I have been able only to touch upon the high points of a federal medical service that provides for a potential load of approximately 14 per cent of the population of the Common-

wealth. Although the hospital service is available, under certain legal and regulatory restrictions, to the entire group, it must be recognized that outpatient care in regularly established Veterans Administration clinics or through private physicians is limited to service-connected disabilities, under existing laws. With the lapse of time, when the number of service-connected disabilities becomes more or less static, the requirement for outpatient care will show a downward trend. On the other hand, with the liberal provisions for hospital care, the demand for such care on the part of veterans will increase through the years. In anticipation of this increased demand, the Veterans Administration has estimated a requirement for 15,000 beds for veteran care in New England by 1965.

The possibility of further amendments of the laws to provide outpatient care for veterans for non-service-connected disabilities cannot be ignored. Continually over the years, since World War I, bills have been introduced before the Congress on this subject. To date, none have been enacted, but the trend is unquestionably in that direction. Such an amendment would have considerable bearing on the distribution of medical care in the Commonwealth and would most certainly require a much wider utilization of physicians on a part-time or fee basis than under existing procedure.

## SURGICAL ASPECTS OF BRONCHIECTASIS\*

JOHN W. STRIEDER, MD †

BOSTON

IT IS generally agreed that the definitive treatment of bronchiectasis is surgical and that most patients should be considered for lobectomy or pneumonectomy, although many may, after evaluation, be denied operation for a variety of reasons.

In 1941 Riggins<sup>1</sup> wrote "The morbidity and mortality of untreated and medically treated bronchiectasis is such that the physician who routinely advises young adults with operable bronchiectasis against surgery, is assuming a large responsibility and in all probability renders his patient a great disservice." Corroboration of this statement is obtained in several recent studies, one of the best of which is presented by Perry and King,<sup>2</sup> who, on the basis of follow-up examination of 400 patients, conclude that in twelve years the mortality in the nonsurgically treated cases was 26 per cent, 41 per cent of the patients dying within five years of onset and 15 per cent living twenty years or longer after

onset. In the fatal cases, 78 per cent of patients died directly of the disease. Some statistical evidence supports the view that patients who develop bronchiectasis before the age of ten do not live beyond the age of forty. Thus, of persons with the onset in the first decade, only 9 per cent were living at the age of forty or over, whereas the onset was in the first decade in only 15 per cent of the 59 patients who reached the age of forty or over. The operative mortality in 122 lobectomies of the modern type, performed by Churchill at the Massachusetts General Hospital on 116 patients, was 3 per cent. The working and living capacity of the living patients who could be traced was considered excellent in 67 per cent of the surgical group and in 38 per cent of the nonsurgical group. These authors find nonsurgical treatment to be only palliative and believe that, because of the steadily decreasing operative mortality, simple lobectomy may be advised without hesitation. Even with bilateral disease the risk in bilateral lobectomy — of course in two or more stages — is often not too great.

\*Part of a symposium on bronchiectasis presented at the annual meeting of the Massachusetts Medical Society, Boston, May 21, 1947.

†Associate professor, Boston University School of Medicine; surgeon-in-chief for thoracic surgery, Boston City Hospital and Mattapan Sanatorium; visiting surgeon in charge of thoracic surgery, Massachusetts Memorial Hospital.

Bradshaw, Putney and Clerf<sup>3</sup> studied 242 patients with bronchiectasis. Of these, 112 were living, and 59 had died from bronchiectasis or its complications.

Riggins<sup>1</sup> found the mortality in 85 cases of medically treated bronchiectasis, collected during ten years but with many of the patients observed for only three or four years, to be 14 per cent. It should be added that children stand thoracic operations exceptionally well, and lobectomy early in life is almost certain to obviate the hazards of bronchiectasis that such children must face if they grow to adolescence or adult life with nonsurgical treatment.

Averaging the figures given by various students of the disease, Hinshaw and Schmidt<sup>4</sup> estimate that less than 10 per cent of patients with severe bronchiectasis obtain a satisfactory result from any form of medical treatment, and conclude that the mortality within ten or fifteen years after the diagnosis is made is somewhere between 30 and 50 per cent.

The development of the modern technic of intralobar dissection and individual ligation<sup>5</sup> has further improved lobectomy as applied to bronchiectasis. Although occasionally it may not prove feasible or may even be impossible in cases of so-called "frozen hilus," because of dense fibrosis resulting from repeated exacerbations of pneumonitis, this technic materially reduces the postoperative complications of empyema and bronchopleural fistula. The advent and increasing availability of penicillin promises a further reduction in the incidence of postoperative empyema. At the Massachusetts Memorial and Boston City hospitals it has been used prophylactically, in many cases both intrapleurally and intramuscularly, as part of the preoperative and postoperative routine, with gratifying results.

Growing knowledge of the surgical anatomy of the detailed structures of the lung, refinements in bronchography and clinical experience have demonstrated that a lobe of the lung is actually made up of a cluster of bronchopulmonary segments. In this connection an important contribution was made by Churchill and Belsey<sup>6</sup> in 1939. They correctly prophesied that the bronchopulmonary segment would replace the lobe as the surgical unit of the lung. Although Nelson<sup>7</sup> had earlier suggested that the lungs are made up of eight lobes—two upper lobes, two middle lobes, the dorsal divisions of the lower lobes and the basal divisions of the lower lobes—it remained for Churchill and Belsey to demonstrate the actual clinical application of this anatomic configuration. They applied the principle of segmental pneumonectomy to resection of the lingula of the left upper lobe ("left middle lobe") by removing the posteromedial segment of the lingula; they also employed the technic in operations on the dorsal divisions of the lower lobes. Such contributions are of value since they point the way to greater conservation of normal pulmonary tissue in cases in which lesions are well localized in a bronchovascular segment of the lung.

## RESULTS OF SURGERY

No discussion of the operative treatment of a disease is complete without reference to the risks involved. Churchill's excellent figures, as reported by Perry and King,<sup>2</sup> were mentioned above. Bradshaw and O'Neill<sup>8</sup> report the results of surgical treatment of bronchiectasis in 76 patients whose disorder was mostly due to an unknown etiologic agent. One death occurred among the 24 patients with disease of the lower lobe and of the lower lobe and lingula—a mortality of 4 per cent. Among 26 patients in whom one lobe was removed but in whom disease was present in other lobes, there were 4 deaths, a mortality of 15 per cent, whereas in 17 patients who had two or more lobes removed there were 3 deaths, a mortality of 18 per cent, 11 of these patients had disease in other lobes. Maier<sup>9</sup> reports 64 cases in which pulmonary resections for bronchiectasis were performed. Lobectomy was done in 55 cases, and pneumonectomy in 9, with 1 operative death—a mortality of less than 2 per cent. Sellors et al.<sup>10</sup> report 100 cases of bronchiectasis operated on by three surgeons employing the individual-ligation technic. Closure of the bronchus was attempted by various means, but no perfect method was found and bronchial fistula of varying size developed in 42 per cent of cases. This is a considerably higher incidence of fistulas than that of most thoracic surgeons in this country. There were 8 deaths, 4 occurring within one month and 4 from four to nineteen months after operation.

Kay and Meade<sup>11</sup> state that pulmonary resection for chronic sepsis with present-day technics, anesthesia and chemotherapy is a safe procedure and can be recommended without hesitation. In 100 cases in which they performed lobectomies, there was only 1 death—an operative mortality of 1 per cent, which compares favorably with that from any other operative procedure.

In a series of 72 patients with unilobar, multilobar, unilateral or bilateral bronchiectasis on whom 93 operations were performed at the Boston City and Massachusetts Memorial hospitals there were 7 operative deaths, a case mortality of 9.7 per cent or an operative mortality\* of 7.5 per cent.

An analysis of the deaths reveals that there were 4 deaths occurring within ten days of operation: 1 of surgical shock twelve hours after left-upper-lobe tourniquet lobectomy, 1 of sepsis and open pneumothorax ten days after left-lower-lobe tourniquet lobectomy, 1 of atelectasis and pneumonitis eighty hours after tourniquet lobectomy of the right middle and lower lobes in a bilateral case, and 1 death on the operating table of tension pneumothorax at the conclusion of a right pneumonectomy. Three deaths occurred forty to eighty days after operation: 1 of *Bacillus suispestifer* (*Salmonella*

\*"Operative mortality" is defined as the percentage of deaths directly attributable to operation.

*choleraesuis*) bacteremia forty days after left-lower-lobe tourniquet lobectomy, 1 of nephrosis and chronic empyema eighty days after the completion of bilateral lobectomy, and 1 of massive hemorrhage from a chronic empyema fifty-two days after completion of bilateral dissection of four lobes

In addition there were 2 deaths from brain abscess eighty-one days and one hundred and twenty-one days respectively after lobectomy in patients who had been discharged from the hospital after the original operation. Both were unilateral cases—1 a dissection lobectomy, and 1 a tourniquet lobectomy. There was also 1 death from massive hemorrhage eighty days after a tourniquet lobectomy of the right middle and lower portions, the patient having been discharged from the hospital after operation.

Of the 41 unilobar cases, in which the total mortality was 4.8 per cent, tourniquet lobectomy was performed in 12, with 2 deaths (a mortality of 16.6 per cent), and dissection lobectomy in 29, with no deaths.

In the 15 unilateral multilobar cases there were 8 bilobar lobectomies with no deaths, and there were 7 pneumonectomies with 2 deaths, or 28.5 per cent.

A survey of the 16 bilateral cases reveals that 7 were completed with 2 deaths (28.5 per cent), in 9 cases in which only the first side was operated on, 1 patient died (11.1 per cent). The total mortality in these cases was thus 18.7 per cent.

Regarding the extent of the bronchiectasis, which can be accurately determined only by adequate bronchograms, I agree with Alexander,<sup>12</sup> who believes that surgery is the treatment of choice for patients whose lesions are restricted to one lobe, to the right lower and middle lobes, to the left lower lobe and lingula ("left middle lobe") or, in some cases, to all the lobes of one lung (total pneumonectomy), to one lobe of each lung or to two lobes of one lung and one lobe of the other (bilateral lobectomy).

Bilateral lobectomy, in stages, has frequently been performed for bronchiectasis. It is routinely considered when the surgical program of suitable bilateral cases is planned. Churchill<sup>13</sup> reports 6 cases, with 1 death. I have performed bilateral excision in 7 cases, with 2 deaths. As might have been expected, however, and as borne out in Bradshaw and O'Neill's<sup>8</sup> report and the figures cited above, bilateral lobectomy is associated with a considerably higher mortality, since it subjects the patient to two major operations. Moreover, the postoperative period after the first lobectomy is rendered more hazardous because the patient must convalesce with disease remaining in one or more lobes.

#### NONSURGICAL MEASURES

Although the present safety of pulmonary lobectomy has solved the problem of treatment for approximately half the patients with bronchiectasis, the other half are, for a variety of reasons (particu-

larly because of extensive bilateral lesions), not suitable for the operation. Alexander<sup>12</sup> has discussed nonsurgical methods of treatment that, if properly and faithfully carried out, can effectively alleviate the distressing symptoms of the disease in a large majority of patients.

Postural drainage is the most valuable of the nonsurgical therapeutic measures. Every bronchiectatic patient should have at least one bronchoscopic examination, not only because some undetected important intrabronchial lesion may be discovered but also because the aspiration of secretions and the chemical shrinkage of the bronchial mucosa often bring about improvement in the symptoms.

Penicillin is of no permanent value in the treatment of advanced bronchiectasis, but if the organisms are sensitive it is of considerable benefit in preparing the patient for operation. It frequently decreases the cough and sputum and increases the sense of well-being, occasionally, it changes the character of the sputum. It is also of value in the treatment of the recurrent pneumonic episodes, as well as in decreasing the amount of sepsis and toxicity during the interval stages.

In the average case of bronchiectasis after penicillin is discontinued the symptoms soon recur. Pulmonary resection should not be withheld when indicated because of the false sense of security resulting from temporary benefit.

#### COMPLICATIONS

##### *Putrid Empyema*

Infection of the pleural cavity by a mixed flora is a not infrequent complication of bronchiectasis. The common organisms found are the anaerobic streptococcus and the fusospirochetal group. Acting in symbiosis, they give rise to a pleuritic exudate, which has been variously termed "foul," "stinking" or "putrid" empyema. In many cases actual perforation of an abscess cannot be demonstrated, and it may be assumed that the infection of the pleural cavity results from the rupture of microscopic subpleural abscesses, or perhaps by actual passage of the organisms across the visceral pleura via the subpleural lymphatic vessels, which has been shown to be operative under similar circumstances by several workers.<sup>14, 15</sup>

Whatever the mechanism involved, when the complication of putrid empyema occurs it must be considered, under most circumstances, an acute surgical emergency, in contradistinction to empyemas of ordinary pyogenic origin.<sup>16</sup> This is particularly true when a perforation assumes a valve-like action, and the problem of tension pneumothorax is added to that of the infection. In these cases only prompt decompression by surgical means can avert a catastrophe.

Even if there is no pyopneumothorax, the almost immediate effect of a virulent pleural infection of this type is frequently that of profound peripheral

vascular collapse, which clinically may be indistinguishable from surgical shock. If the diagnosis is suspected, it can be confirmed at once by thoracentesis and the aspiration of putrid, thin pus. When such a finding is made, surgical drainage, amply wide and open, must be undertaken forthwith. Strieder and Lynch<sup>16</sup> have shown that when prompt open drainage is established in putrid empyema, whatever its cause, the mortality drops from the rate of approximately 50 per cent prevailing when less drastic measures are used to about 14 per cent.

### Extension of Infection

Extension of the infection, either directly into the contiguous lung parenchyma from bronchiectatic abscesses or by bronchogenic dissemination into the same or a contralateral lung, is a common cause of death in bronchiectasis. In many cases this is due to the inexorable progression of a virulent infection in a host whose tissues offer inadequate resistance. In others, the difficulty stems from the impaired efficiency of the cough mechanism, as a result of which the copious, infected secretions bathing the tracheobronchial tree are not expelled. If a patient is unwilling or unable to cough efficiently because of debility or postoperative pain, frequent intra-tracheal catheter suction or bronchoscopic aspiration of secretions may suffice to tide him over the critical period until the cough mechanism is again functioning normally. Loss of effective ciliary action by the bronchial mucosa, which normally tends to lift secretions away from the pulmonary periphery, undoubtedly contributes to stagnation of secretions and their gravitation into the alveoli.

It is therefore of the utmost importance, both preoperatively and postoperatively, to employ all the available measures (forced cough, postural drainage, catheter suction and bronchoscopy) to promote evacuation of secretions and to prevent stagnation and gravitation to uninvolved portions of the lung.

### Metastatic Brain Abscess

Metastatic brain abscess frequently occurs as a complication of thoracic suppuration, in my own experience it has been uniformly and rapidly fatal. In a recent comprehensive paper, Collis<sup>17</sup> states that only 2 recoveries have been recorded after surgical drainage of brain abscesses secondary to thoracic disease. In his series, this cerebral complication occurred in 4.5 per cent of cases of lung abscess and accounted for 20 per cent of the mortality from lung abscess. There is also some evidence that its incidence has risen with the increase in operative procedures in thoracic suppuration. The experience of Collis is in accord with that discussed above in the over-all mortality for 93 operations for bronchiectasis. Of the total of 10 deaths (7 operative), 2 resulted from brain

abscess and occurred eighty-one and one hundred and twenty-one days respectively after operation.

### Hemorrhage

Hemorrhage is not an unusual complication of bronchiectasis. When it occurs before operation, as hemoptysis, it is usually mild, but it may at times assume alarming, although rarely fatal, proportions. Frequent hemoptysis is a definite indication for surgery in patients in whom there is, at the same time, no contraindication.

As a postoperative complication of tourniquet lobectomy hemorrhage was a dreaded and, when it occurred, rapidly fatal incident. It resulted from imperfect hemostasis of the lobar or pulmonary pedicle or from latent sepsis with delayed erosion of a large vessel of the pedicle. Fortunately, the modern dissection-ligation technique, whereby the hilar vessels of the lung or lobe are individually treated, has to a large extent obviated this complication.

### SUMMARY

The majority of patients with bronchiectasis should be considered for lobectomy or pneumonectomy although many may, after evaluation, be denied operation for a variety of reasons.

The operative results of 93 operations on 72 patients who had bronchiectasis are discussed.

The major complications of bronchiectasis are briefly reviewed.

## MECHANISMS UNDERLYING PULMONARY AND CARDIAC COMPLICATIONS OF ELECTRICALLY INDUCED CONVULSIONS\*

M D ALTSCHULE, M.D.,† AND K J TILLOTSON, M.D.‡

BOSTON

THE changes in pulmonary function observed during electrically induced convulsions account for the development of atelectasis and, more rarely, lung abscess in patients receiving electroshock therapy. A convulsion induced by electric shock is ushered in by maximal forced expiration, which is then maintained throughout the seizure.<sup>1-3</sup> Roentgenograms made at the height of the tonic phase of

During the seizure profuse salivation occurs, apparently as a consequence of autonomic stimulation, in addition it is possible that the marked elevations in blood carbon dioxide tension<sup>3</sup> and blood lactic acid<sup>4</sup> that have been noted stimulate increased secretion of the salivary glands.<sup>5</sup> Roentgenograms made during seizures suggest that bronchial secretion is likewise increased at this time (Fig 1). Maximal

FIGURE 1 Elevation of the Diaphragm during Electrically Induced Convulsions

A demonstrates a roentgenogram of the chest immediately before electroshock and B one at the height of the tonic phase of the seizure twenty seconds after the start of the convulsion.

such seizures uniformly show an extreme degree of elevation of the diaphragm, together with some narrowing of the intercostal spaces, marked compression of the lung results (Fig 1). With the end of the convulsion the patient relaxes, and the lungs re-expand to approximately their normal size.

inspiration, such as that occurring at the end of the seizure,<sup>2</sup> causes the aspiration of some of this material into portions of the previously compressed lung, and small bronchi may become occluded, failure of portions of the lung so blocked off to re-expand causes the atelectasis that may be found. It is probable that patchy atelectasis is more common than is usually recognized, for the condition gives rise to no symptoms and clears up in a few days. On the other hand, if infection localizes in an atelectatic area development of an abscess may

result. This complication is rare, however, having occurred only once in 200 patients given electroshock therapy during the last five years (Fig 2).

The following case is regarded as typical.

E W G, a 65-year-old unmarried typist, entered the hospital voluntarily on October 11, 1946, complaining of agitation and depression of 6 months' duration. A diagnosis of involutional melancholia was made, and physical and laboratory examinations showing no evidence of organic

FIGURE 2 Lung Abscess, Absent before Treatment, Detected after Eighth Shock

disease, electroshock therapy was recommended. Because roentgenograms demonstrated an old compression fracture of the spine and deformity of the pelvis apparently consequent to a serious accident 19 years previously, curare (Intocostin\*) was used.

Treatments were begun on October 21 and given 3 times weekly; respiration was not depressed after the treatments. Improvement was rapid, but after the eighth treatment on November 6 the patient was noted to have fever, chilly sensations and a slight cough, and treatments were stopped. The cough was productive of a small amount of foul sputum, which the patient swallowed.

Physical examination was not remarkable except for a temperature of 101°F; roentgenograms showed an abscess of the lung. On November 14 penicillin in doses of 100,000 units given intramuscularly every 3 hours was started, and 2 days later the temperature was normal. The white-cell count varied between 9800 and 17,000 during the next few weeks. On January 4, 1947, the penicillin dosage was changed to 100,000 units in wax once daily. On January 10 the patient was considered cured clinically and by x-ray study. During the period of the pulmonary infection the depression recurred in a severe form. Another course of electroshock therapy with curare in March and April resulted in clinical cure, no pulmonary complications developed.

\*Kindly supplied by E. R. Squibb and Sons, New York City.

The reported exacerbation of latent tuberculous infection may be based on similar mechanisms and also on the tearing of brittle fibrous patches containing tuberculous organisms.

The marked changes in intrathoracic pressure that favor the occurrence of pulmonary lesions serve, on the other hand, to protect the heart during electrically induced seizures. The increase in intrathoracic pressure exerts a force on the outside of the coronary arteries that prevents an increase in difference between the internal and external pressures on the walls of these vessels and may even cause a decrease; brittle coronary arteries are thereby protected from damage. In addition the change from the normal negative intrapleural pressure to a positive pressure during the seizure retards the pas-

FIGURE 3 Rise in Peripheral Venous Pressure during Eight Electroshock Treatments

The solid line indicates readings during the seizure, and the dotted lines those made after the seizure.

sage of blood from the periphery into the heart, this change is reflected in the increase in peripheral venous pressure noted during electrically induced seizures<sup>2, 6</sup> (Fig 3). As a consequence of the diminished venous return of blood the heart becomes smaller than normal (Fig 1), and its work is decreased. Accordingly, it is apparent that the great increase in metabolism that occurs during the thirty or forty seconds of a convulsion is not associated

with a corresponding increase in strain upon the heart at that time. After the end of the convulsion, the cardiac work is increased, judging by the acceleration of circulation time.<sup>7</sup> However, this increase in the work of the heart is related in large part to the discharge of the accumulated oxygen debt, a process that requires many minutes, the cardiac work corresponding to the metabolic increase brought about by the convulsion is therefore not concentrated in the brief period of the seizure but is spread over a longer period and, accordingly, usually does not reach a dangerous level at any one time. Nevertheless, myocardial infarction has been reported to occur in relation to electroshock therapy, the damage probably is done shortly after rather than during the convulsion. Another factor making for a transient increase in cardiac work at this time is the return to the heart of the blood impounded in the periphery during the seizure, this release of blood occurs almost entirely during the first minute after the convulsion, for the venous pressure falls almost to normal during that time (Fig. 2).

In the following case electroshock therapy apparently aggravated the effects of an already present coronary sclerosis.

A H. L., a 52 year-old executive, became depressed in January, 1945, and because of the marked progression of his symptoms sought psychiatric advice in November of that year. The past history was not contributory except for mild hypertension. On November 1 an electrocardiogram was normal except for left axis deviation and inverted P and T waves in Lead 3. The patient was given five electroshock treatments without untoward event in November and improved markedly. However, he noted for the first time the development of squeezing precordial exertional discomfort, aggravated by exposure in cold and relieved by rest. Physical examination at that time was not remarkable except for a blood pressure of 168/110. Electrocardiograms in March, 1946, showed left axis deviation and an inverted T wave in Lead 1. Roentgenograms 3 months later revealed prominence of the left ventricle and hypertrophic changes in the spine. Electrocardiograms at that time disclosed a sinus bradycardia (the rate being 50), left axis deviation and a T wave in Lead 1. The two-step stair test, performed in a cold room, caused dyspnea and reproduced the precordial discomfort that the patient had experienced spontaneously during his normal activities. It was concluded that he had developed angina pectoris and changes in the electrocardiogram after electroshock therapy and therefore fell into the small group of patients in whom the effects of coronary sclerosis were aggravated by induced seizures.

The rush of blood from the periphery into the right auricle and great veins of the thorax during the post-convulsive period probably accounts for the cardiac arrhythmias that may occur at that time, the rhythm is normal during at least the last half of the seizure (Fig. 4). The arrhythmias are vagal in type<sup>8</sup> and are apparently consequent to reflexes activated by sudden distention of the auricles and great thoracic veins.<sup>9</sup>

It is apparent that diminution of the postconvulsive strain upon the heart would be accomplished by a decrease in the oxygen debt developed and in the amount of blood incarcerated in the periphery

during the seizure. This can be effected by the use of a suitable preparation of curare, it is possible to administer electroshock therapy to patients of advanced age and with electrocardiographic evidence of cardiac damage through the use of this drug.<sup>10</sup> It must be borne in mind that a solution of d-

FIGURE 4 Continuous Strip of Electrocardiogram, Showing Absence of Arrhythmia during the Seizure

Normal electrocardiographic complexes are interspersed among action currents resulting from clonic muscular contractions

tubocurarine is the drug of choice, since Intocostrin may contain impurities that exaggerate to a dangerous degree the vagal impulses that influence cardiac rhythm.<sup>11</sup>

## ANGIOCADIOGRAPHY · ITS USE IN THE DIAGNOSIS OF PATENT DUCTUS ARTERIOSUS\*

ROBERT A. FURMAN, M.D.†

CLEVELAND, OHIO

**ANGIOCADIOGRAPHY**—contrast visualization of the heart and great vessels—was first made a practical procedure by Robb and Steinberg<sup>1</sup> in 1938. In subsequent reports these authors have described in detail their technic of employing serial roentgenograms after the rapid intravenous injection of 70 per cent Diodrast<sup>2</sup> and, along with many others, have reported their observations in normal and pathologic cardiovascular systems. It is the purpose of this report to review briefly the clinical applications of angiocardiology, to discuss the use of this technic in a rural hospital and to report its use in the diagnosis of a case of patent ductus arteriosus.

### CLINICAL APPLICATIONS

Angiocardiology has, in general, two great advantages: it enables one to outline and differentiate the various components of the cardiac and great-vessel silhouettes, and it makes possible the differentiation of vascular and nonvascular mediastinal shadows. This technic has been employed profitably in the more academic study of normal hearts<sup>3</sup> and of various types of acquired cardiovascular disease—rheumatic,<sup>4</sup> arteriosclerotic,<sup>5</sup> hypertensive,<sup>6</sup> syphilitic<sup>6</sup> and pulmonary.<sup>6</sup> Its more practical use has been reported in cases of the superior-vena-cava syndrome,<sup>7</sup> demonstrating the site of an arteriovenous fistula of the subclavian vessels<sup>8</sup> and in differentiating aneurysms of the great vessels from other mediastinal masses.<sup>9</sup> Steinberg,<sup>10</sup> however, has mentioned 2 cases in which the dye did not fill the aneurysms sufficiently for their demonstration.

In congenital cardiovascular lesions, cases have been studied and reported of dextrocardia<sup>11</sup> and intracardiac shunts.<sup>12</sup> The greater value of angiocardiology, however, is in cases of congenital lesions amenable to surgery. By this technic it has been possible to demonstrate definitely the lesions in pulmonic stenosis<sup>13</sup> and coarctation of the aorta.<sup>14</sup> The findings in cases of patent ductus arteriosus are discussed below. Its use has not yet been reported in anomalies of the aortic arch of the type whose surgical treatment has been reported by Gross and Ware,<sup>15</sup> but again the abnormality could be exactly demonstrated. It is true that in typical cases of all four lesions the diagnosis can be made by careful clinical and roentgenographic examination. But the 2 cases of coarctation described by Grishman et al.<sup>14</sup>

were atypical ones diagnosed as rheumatic heart disease and hyperthyroidism before the lesions were demonstrated by angiocardiology. In the case of patent ductus reported below, it is believed that the diagnosis could not have been established without angiocardigraphic studies. It is also true that in cases of pulmonic stenosis and patent ductus the diagnosis can be made most accurately by cardiac catheterization,<sup>16</sup> but this is an intricate procedure and is not always available. Because of the great benefit of surgery to patients with these four lesions, it seems imperative to employ angiocardiology in atypical or suspected cases, so that no patient may be denied surgery for want of an accurate diagnosis.

In the 27 cases of patent ductus arteriosus studied by Steinberg et al.,<sup>17</sup> a distinct localized dilatation of the aorta was noted in 26. The ductus itself could not be opacified. The authors postulated that this dilatation represented either the infundibulum of the ductus, always known to be funnel shaped at its aortic end, or a traction aneurysm of the descending aorta at the base of the ductus, as originally described by Thoma. In 3 of the 12 cases in which the diagnosis was confirmed by operation, silver clips were placed on top of the ductal ligatures. Repeat angiocardigrams in these cases showed the clips to be in the exact location of the aortic dilatation. In the case in which the aortic lesion was not demonstrable, it seems possible that the clinical diagnosis might be questioned in the absence of a machinery murmur or thrill and in the presence of a peculiar axis deviation by electrocardiogram. A "slight dilatation of the descending portion of the aorta" was noted in only 1 other of the many patients examined by Steinberg et al. This patient was later found at autopsy to have an interventricular septal defect occluded by bacterial vegetations and pulmonic insufficiency secondary to an anomalous posterior pulmonic-valve leaflet (Case 3).<sup>12</sup>

### ANGIOCADIOGRAPHY IN A RURAL HOSPITAL

When this technic was employed for the first time, there were two considerations: the precautions that must be taken to make the procedure safe, and whether the method could be employed with the equipment available.

To determine what precautions should be taken, the American literature on fatalities from the administration of 35 per cent Diodrast was reviewed. Pendergrass et al.,<sup>18</sup> in their extensive review, reported 26 cases, and reports of 10 others are to be found in the literature. Of this entire group,

\*From the Mary Imogene Bassett Hospital, Cooperstown, New York.  
†Intern, University Hospitals.

11 can only be mentioned because of insufficient data, and in 10 others Diodrast could not be identified with certainty as the agent responsible for the death. In the remaining 15 cases, death was due to a sudden anaphylactoid or shock-like response in 10<sup>18-21</sup> (Cases 1, 2, 3, 6, 7 and 10);<sup>18</sup> to acute anuria in 2, presumably caused by the effect of Diodrast on previously diseased kidneys that had blocked its rapid excretion (Cases 4 and 19)<sup>18</sup> and to a delayed type of anaphylactoid response in 3 cases, caused in

best not to attempt angiocardiology. If the history of allergy is only slightly positive, studies might be attempted after the prophylactic use of adrenalin<sup>18</sup> or perhaps Benadryl. Also, in view of the cases reported by Dolan<sup>20</sup> and Shanahan,<sup>22</sup> a history of iodide sensitivity should be sought in every case.

Of the sensitivity tests, the best at present appear to be the oral<sup>20</sup> and the ocular.<sup>23</sup> Evidence on the reliability of the skin tests is quite conflicting, but

A

B

FIGURE 1 Angiocardiogram (A) and Tracing Made from it (B) Taken in the Left Anterior Oblique Position Two and a Half Seconds after the Injection of Diodrast

SVC = superior vena cava RAA = right auricular appendage RA and RV = right atrium and ventricle RPA = right pulmonary artery, in cross section and LPA = left pulmonary artery in longitudinal section. Note the enlargement of both pulmonary arteries

2 (Cases 9 and 17)<sup>18</sup> by the delayed excretion of Diodrast by previously diseased kidneys.<sup>24</sup>

These deaths due to Diodrast therefore appear to have been caused either by an anaphylactoid response or by the effect of Diodrast on pre-existing renal disease causing delayed excretion or by a combination of the two. To eliminate patients who may have an anaphylactoid response there are two avenues of approach: a careful history of allergy, personal or familial, and sensitivity tests. Although the value of the former appears uncertain at present, it should be taken, and if strongly positive, it seems

on the basis of Taylor's<sup>25</sup> findings of a lack of correlation between the minor toxic reactions and the intracutaneous test, the test is believed to be of questionable value.

To eliminate patients who would have a delayed Diodrast excretion, the standard phenolsulfonephthalein excretion test is the most satisfactory, because of the similarity of the mode of renal excretion of the drug and Diodrast, both being filtered and secreted. Bishop's<sup>26</sup> standards of an excretion of greater than 15 per cent in fifteen minutes and 30 per cent in one hour were arbitrarily

accepted. Also adopted was the suggestion, made by the Council of Pharmacy and Chemistry of the American Medical Association when the administration of 70 per cent Diodrast was approved, that the drug be withheld from patients with clinical evidence of hyperthyroidism or hepatic disease.<sup>25</sup>

It was therefore believed that the procedure would be a safe one if each patient fulfilled the following four criteria: a negative history of allergy or iodide sensitivity, negative oral and ocular Diodrast sensitivity tests, a phenolsulfonephthalein excretion of greater than 15 per cent in fifteen minutes and

springs had been removed. An assistant simply pushed a cassette into place after the exposure of the one in the machine, the latter being caught by another assistant as it was ejected. With this method six films were taken in ten seconds with but one practice run. The films were protected before and after exposure by two lead aprons suspended from a cross bar placed over the stereoscopic machine. A small table with two bookends kept the cassettes readily available for the person responsible for placing them in position. The technic employed was otherwise identical with that described by

A

B

FIGURE 2 Angiocardiogram (A) and Tracing Made from it (B), Taken in the Left Anterior Oblique Position Eleven Seconds after the Injection of Diodrast

LV = left ventricle, AAC = area of the aortic cusps, and TA = traction aneurysm of the descending aorta.

30 per cent in one hour, and no clinical evidence of hyperthyroidism or hepatic disease.

The technical problems faced were two: the injection of 50 cc of Diodrast within two seconds and the taking of serial roentgenograms in the ten seconds normally required for the passage of the dye through the heart and great vessels. The first of these was solved by the purchase of a 13-gauge transfusion needle (the only expense) and by manual filing of the bore of a 50-cc syringe until it was larger than that of the needle. The second was solved by manual passing of the cassettes through the apparatus used for taking stereoscopic films, from which the ejector lever and restraining

Robb and Steinberg,<sup>2</sup> except that an infusion was kept running through a three-way stopcock, after insertion of the needle, to ensure its patency while the circulation time was determined and positioning films were taken. It should be emphasized that anyone using this technic should be thoroughly familiar with the detailed directions outlined by Robb and Steinberg.

#### CASE REPORT\*

C L, a 30-year-old laborer, was first seen at this hospital at the age of 21 for evaluation of "valvular heart trouble." At the age of 9 a "loud heart murmur" had been heard for the first time. During the next 12 years the patient had followed

\*This case is reported through the courtesy of Drs. George M. Mackenzie and George H. Humphreys. 11

a vigorous athletic program and did not believe that his exercise tolerance had been less than that of any of the other boys. There was no history of acute rheumatic fever, scarlet fever, tonsillitis, chorea, arthritis, growing pains, precordial pain, edema or cyanosis. Physical examination at that time revealed a well developed and well nourished young man with no evidence of cyanosis, clubbing or edema. The cardiac apex was percussed 11 cm. in the fifth left interspace. No thrill was palpable. There was a regular sinus rhythm. At the base of the heart and in the area between the clavicle and the cardiac border was a continuous murmur with a systolic accentuation. This was heard with diminishing intensity down over the precordium becoming separate diastolic and systolic murmurs in the third and fourth interspaces along the left border of the sternum. The murmur was transmitted somewhat into the vessels of the neck. There was no evidence of collateral circulation and strong pulsations were palpable in the legs. Physical examination was otherwise negative. At the time the electrocardiogram was being taken, the murmur was completely absent, returning later in the afternoon as noted above. The electrocardiogram revealed slight slurring of the QRS complexes in all leads and an inverted T wave in Lead 3. There was slight left axis deviation but no other abnormalities were noted. A 6-foot film of the heart showed a somewhat rounded left cardiac border, suggesting an enlarged left ventricle. The total transverse measurement of the cardiac shadow was 140 mm. the internal thoracic diameter being 295 mm.

The patient was referred to the hospital because of pyrexia of 6 weeks duration. During the intervening years he had had no cardiac or respiratory symptoms. He was employed at heavy manual labor and was playing semiprofessional baseball. There was no history of recent dental extraction or trauma. Six weeks before admission he had suddenly experienced a shaking chill and had subsequently felt alternately hot and chilly with a persistent afternoon fever.

The patient appeared ill and had a café-au-lait complexion. There was no cyanosis, clubbing or edema. No precordial shock or thrills were palpable. The left border of the heart was percussed 12.5 cm. in the fifth left interspace. There was a regular sinus rhythm. Along the left border of the sternum at the level of the second and third interspaces was a "whirling huzzing systolic-diastolic murmur. Another observer described it as a loud rough systolic murmur. There was also a rasping, nontransmitted apical systolic murmur. The spleen was not palpable and there was no evidence of embolic phenomenon.

The temperature was 103°F. and the blood pressure was 128/66 in the arms and 144/69 in the legs. There was no fall in diastolic pressure after exercise.

A blood culture taken on the day of admission grew colonies of alpha hemolytic streptococcus in all flasks. The white cell count was 14,000, with 68 per cent neutrophils. The electrocardiogram was essentially unchanged from the record taken 9 years before. Roentgenographic and fluoroscopic examinations revealed enlargement of the left and right ventricles with no evidence of enlargement of the left auricle, pulmonary arteries and aorta. There was no hilar dance. The transverse diameter of the heart was 154 mm. Further laboratory studies revealed an ether circulation time of 5.5 seconds, with no Hitzig phenomenon, negative oral and ocular sensitivity tests to Diodrast and a phenolsulfone phthalein excretion of 28 per cent in 15 minutes and 55 per cent in 1 hour.

The patient was hospitalized for 5 1/4 weeks receiving a total of 56,000,000 units of penicillin. He was afebrile from the 4th day on, with the exception of spikes in temperature to 102°F. on the 12th and 23rd days. All blood cultures taken after the institution of penicillin therapy were negative.

### DISCUSSION

During the patient's stay in the hospital the question arose of referring him for surgery, but no definite decision was reached because the diagnosis was not clear cut. Of the ten criteria for the diagnosis of patent ductus listed by Shapiro,<sup>1</sup> this patient definitely had three, four were definitely absent, and three were questionable. He did have an enlarged heart, absence of cyanosis or clubbing

and a history of heart disease from early childhood. He did not have a thrill in the pulmonary area, an enlarged pulmonary artery, enlarged and pulsating pulmonary vessels or any stunting of growth. It was questionable if he had a machinery murmur, an increased pulse pressure and a normal electrocardiogram.

In the hope of being able to offer more conclusive evidence of the existence of a patent ductus arteriosus, angiocardigraphic studies were performed, with particular attention to the following possibilities: enlargement of the pulmonary arteries, previously not visualized by fluoroscopic examination, and the traction aneurysm of the aorta mentioned above. Prior to examination a normal subject was studied to perfect the technique and to obtain films for comparison.

The angiocardigrams of the patient in the case reported above and tracings made from them are presented in Figures 1 and 2. Both films were taken in the left anterior oblique position. The first, taken two and a half seconds after the start of the injection, shows definite enlargement of both branches of the pulmonary artery. The second film, taken eleven seconds after the start of the injection, reveals a definite fusiform dilatation of the descending aorta, just below the arch and on the side facing the pulmonary arteries. This was also visible in the films taken immediately before and after the one described above. On the basis of these two findings, the diagnosis of patent ductus arteriosus was regarded as confirmed. The patient was referred to Dr. George H. Humphreys, II, who, at operation, found and ligated a patent ductus.

### SUMMARY

The clinical applications of angiocardiology are briefly reviewed, with emphasis on its use as a diagnostic aid in atypical cases of congenital cardiovascular lesions amenable to surgery.

The use of this technique in a rural hospital is discussed, the four criteria a patient should fulfill prior to angiocardigraphic studies being listed, and the methods by which the difficulties of rapid intravenous injection and rapid serial roentgenograms were overcome being described.

An atypical case of patent ductus arteriosus is reported in which the clinical diagnosis was confirmed by angiocardigraphic studies, demonstrating enlargement of the pulmonary arteries and a traction aneurysm of the descending aorta. This diagnosis was confirmed at operation.

I am indebted to Dr. James Drorbaugh and Mr. Ivan Lawrence for assistance in performing these studies.

## ACUTE HEMOLYTIC ANEMIA FROM QUININE USED AS AN ABORTIFACIENT\*

A T LICCIARDELLO, M D,† AND J B STANBURY, M D ‡

BOSTON

ACUTE hemolytic anemia following the administration of quinine has rarely been observed except in the presence of malaria Terplan and Javert<sup>1</sup> found 8 cases in the literature and reported a case of their own All these patients were women who had taken or been given the drug as an abortifacient All died They showed evidence of a severe degree of intravascular hemolysis and, in most cases, hemoglobinuria When measured, the nonprotein nitrogen content of the blood was found to be very high The intake of the drug was not always beyond usual therapeutic dosage as little as 0.4 gm proved fatal in 1 case Vartan and Discombe<sup>2</sup> have added another fatal case After the ingestion of 6 gm of quinine sulfate to induce abortion, the patient quickly developed icterus and black, scanty urine The terminal blood urea nitrogen was 540 mg per 100 cc Hemoglobin casts were found in the kidney at autopsy The case of a patient who recovered has been reported<sup>3</sup> She was a twenty-year-old girl who, after taking an unknown amount of quinine to cause abortion, developed jaundice, hemoglobinemia, hemoglobinuria, oliguria and uremia She recovered after resumption of renal function

The mechanism of the hemolytic process is not clear Acute intravascular hemolysis following quinine has been reported apparently only in the presence of malaria or pregnancy Ponder and

Abels<sup>4</sup> found that in rabbits quinine in very large dosage produced a slight fall in red-cell concentration and made the erythrocytes more susceptible to saponin and taurocholate hemolysis The quantity of quinine necessary was far beyond that which has produced severe hemolytic anemia in man Perhaps the quinine renders the red cell more susceptible to hemolysins that may be present during malaria and pregnancy In animal experiments Nocht and Kikuth<sup>5</sup> have shown that very small amounts of quinine may facilitate amboceptor hemolysis

We have recently observed a similar patient who made a complete recovery from severe intravascular hemolysis following quinine This case is as follows

The patient (M G H 526650), a 42-year-old mother of 8 children, entered the hospital on April 14, 1946, because of the sudden appearance of dark-red urine and profuse vaginal bleeding She described a normal menstrual history Two weeks before entry, at the time of an expected period, she began to have a spotty vaginal discharge This continued until 2 days before entry, when she felt chilly and weak and ached all over On the following morning she was surprised to find that the urine was dark red She began to have profuse vaginal bleeding and passed many clots The family noticed that the skin had become slightly yellow She continued to bleed all day and through the night, and on the morning of admission she passed a piece of tissue accompanied by many blood clots

The patient had been born near Naples and had come to the United States in 1919 The only history suggestive of malaria was that she had had "Spanish flu" as a girl in Italy during an epidemic There was no history of familial jaundice, anemia or dark urine either in the patient or in her family, many of whom were available for questioning She vehemently denied any suspicion of pregnancy or drug ingestion other than that of a few aspirin tablets taken for

†Formerly fourth-year student, Harvard Medical School

‡Resident, Medical Service, Massachusetts General Hospital

headache on the evening before entry. She had eaten no fava beans. Six pregnancies had been normal. She had had one miscarriage at 6 months following prolonged bleeding, and one threatened miscarriage. One of her children had been born prematurely.

The patient was obese, moderately icteric and acutely ill. She was dyspneic and apprehensive. The liver was slightly tender, and the edge palpable 3 cm. below the costal margin. The spleen could not be felt. There was tenderness over a small area in the left groin. There was a small amount of vaginal bleeding. The uterus was anterior, freely movable and  $1\frac{1}{2}$  times the normal size. There was moderate tenderness in both vaults.

The temperature was  $102.6^{\circ}\text{F}$ , the pulse 100 and the respirations 35. The blood pressure was 120/74.

A catheter specimen of urine was wine red and contained 103 mg. of oxyhemoglobin per 100 cc. There were no formed elements in the sediment. There was a +++ test for albumin. The serum of a freshly drawn and centrifuged specimen of blood was the same color as the urine. On analysis several days later it contained 516 mg. of methemoglobin per 100 cc. The red-cell count, which on entry was 4 100 000 fell to 2 800 000 8 hours later. The white-cell count was 50 700 with 86 per cent neutrophils. These showed toxic granulation. The red cells showed great variation in size and shape and moderate spherocytosis. Complete hemolysis of the red cells occurred when they were mixed with 0.55 per cent physiologic saline solution and partial hemolysis with 0.60 per cent, as compared with normal controls of 0.38 per cent and 0.42 per cent. The osmotic fragility had returned to normal on the 5th hospital day, with complete hemolysis at 0.38 per cent and partial hemolysis at 0.40 per cent. Tests for cold agglutinins, hemolysins and acid hemolysis and a Donath-Landsteiner test done by Dr. Charles P. Emerson, of the Thorndike Memorial Laboratory were negative. Numerous blood smears for malaria were also negative. A blood Hinton test was negative. Urine obtained on the day of admission contained 13 mg. of quinine per liter.

Jaundice disappeared by the 3rd hospital day. The non-protein nitrogen began to rise on the 2nd hospital day, and by the 5th day had reached a level of 150 mg. per 100 cc.

where it remained for 7 days. The carbon dioxide combining power of the blood fell to 18 milliequiv. per liter. Throughout that period the patient complained of headache, vomited frequently and continued to discharge necrotic tissue and blood through the vagina. This tissue proved to be placental in origin. The discharge continued until dilatation and curettage were done on the 17th hospital day. The urine output averaged about a liter per day, and the specific gravity remained close to 1.010. The nonprotein nitrogen slowly fell to normal by the 3rd hospital week. After the curettage the temperature, which had risen to  $101^{\circ}\text{F}$  daily, returned to normal. In a few days it rose again, and heavy cultures, which had previously been sterile, showed a heavy growth of *Escherichia coli*. A 4-day course of streptomycin (1 gm. daily) was followed by relapse. Persistent clearing of the urine and freedom from fever followed a 10-day course. The patient was discharged on the 44th hospital day when the red-cell count was 4 000 000.

Two weeks after admission she admitted having taken nine large capsules containing a white powder given her by a friend to interrupt a suspected pregnancy.

This report serves to call attention to the fact that quinine is an occasional cause of severe hemolytic anemia associated with jaundice and hemoglobinuria and to emphasize the danger of quinine as an abortifacient.

## MEDICAL PROGRESS

### SYPHILIS

G. MARSHALL CRAWFORD, M.D.\*

BROOKLINE, MASSACHUSETTS

#### SEROLOGIC PROBLEMS

A diagnosis of syphilis made on purely serologic grounds is to be avoided if possible, nevertheless, the necessity of relying on serologic findings is all too often inescapable. A good example of a typical situation is a survey of 82,070 consecutively examined male maritime enrollees, aged sixteen to fifty-four years.<sup>1</sup> Among this clinically healthy population, there were 783 with positive reactions to the Kahn standard serologic test for syphilis. In 47 per cent of these 783 men a diagnosis of syphilis was eventually made, weakly positive reactions proved to mean syphilis in only 20 per cent of this group, whereas strongly positive reactions indicated

syphilis in 80 per cent. Of the 783 original positive reactors, 40 per cent had but a single positive test and were proved not infected. The remaining 13 per cent had nonsyphilitic persistently false-positive reactions. This seems to be an unusually high percentage of persistently false-positive serologic tests for syphilis.

#### False-Positive Reactions

Many articles have been written regarding the false-positive reaction, and the list of diseases most commonly producing this phenomenon is well known. Nevertheless, it will again bear repetition. The highest percentage of positive reactions are found in the three syphiloid diseases, yaws, bejel and pinta. Leprosy, malaria, vaccinia and infectious mononucleosis are probably next in order of frequency.

\*Acting head, Department of Dermatology, Harvard Medical School; acting head, Department of Dermatology, Massachusetts General Hospital.

Technical errors are by no means rare. The so-called "biologic false-positive reactions" seem to be found with distressing frequency and are as yet not adequately explained. Many diseases have been reported from time to time as causing occasional false-positive tests for syphilis, including such conditions as upper respiratory infections, virus pneumonia, lymphogranuloma venereum, hyperpyrexia from various causes, serum treatments and assorted immunization procedures. It is also claimed that weak false-positive reactions may be caused by tuberculosis, pregnancy and cancer.<sup>43</sup> If they do occur, the incidence of false-positive reactions from these last three conditions is extremely low. False-positive reactions have also been reported in diseases associated with hyperproteinemia, such as kala-azar.<sup>44</sup> Disorders with associated hyperproteinemia do not necessarily lead to false-positive reactions, however, some may, but there are numerous others that do not. Lupus erythematosus is another disease that apparently must be added to the list. Occasional cases showing false-positive tests for syphilis have been reported from time to time and more frequently in recent years. A recent article describes a group of 3 patients, one of whom came to autopsy, 2 cases of the chronic discoid form of the disease were verified histopathologically, and the third was a case of acute disseminated lupus erythematosus that was examined post mortem.<sup>45</sup> All 3 showed false-positive reactions to syphilis at one or another time during the course of observation.

It seems apparent that nonspecific serologic tests for syphilis, considered uncommon in the past, are now becoming more numerous, particularly in precipitation and flocculation tests such as the Kahn, Kline, Eagle and Mazzini.<sup>46</sup> Moreover, it is suspected that nonspecific positive reactions occur in spinal fluids, and it is suggested that they be considered in early untreated cases in which the cell count, globulin and colloidal gold are normal and only the serologic tests positive. A thoroughly conservative attitude is obviously warranted in the serologic diagnosis of latent syphilis when no history of the disease exists.

There are some circumstances under which a false-positive blood serologic test for syphilis should be particularly suspected. In the complete absence of other evidence of the disease a disagreement in results of complement-fixation and precipitation tests should warrant suspicion, especially if only the precipitation reaction is positive. When quantitative tests are employed and provide fluctuant or low-titer reactions on repetition and if there is a decline toward negativity over a period of several weeks, the patient is probably not infected. If there has been an acute infection of any sort within thirty to sixty days prior to the suspected test, prolonged repetition is warranted, especially if a precipitation reaction alone is used. It is never desirable to depend on a single test under such cir-

cumstances, the use of several types of determinations is indicated, as well as the employment of more than one laboratory.

### *Verification Reactions*

A number of "verification" or differential tests have been devised to distinguish between syphilitic and nonsyphilitic reactions. The value of these procedures has not been established, and they are not routinely employed in laboratories for this purpose. They are applicable only to research problems and require a great deal more study before they can be recommended.

### *Quantitative Reactions*

The quantitative determination of reagin titer in a patient's serum is an entirely different procedure and has certain valuable application. Perhaps the greatest value of the quantitative test is in the follow-up study of infants born of syphilitic mothers. There may be a carry-over of the mother's reagin in the child's blood, and a steady drop in reagin titer will indicate that the child itself is not infected, the reverse (when the titer rises or remains persistently elevated) is proof of congenital syphilis. Quantitative tests may be helpful in suspected biologic false-positive reactions, a persistently high reagin titer should indicate syphilis, whereas a slowly dropping titer (without treatment) or fluctuating readings may well mean a biologic false-positive reaction. A third use for the quantitative determination is in the so-called "Wassermann-fast" or seroresistant patients. Quantitative tests may show slow changes that would not otherwise be detectable. An important but strictly experimental application of quantitative serologic tests lies in the evaluation of new antisyphilitic drugs. A most comprehensive study of differential reactions has been carried out at Duke University.<sup>47-52</sup> This work, which is reported in a series of six papers essentially comprising a monograph, represents a tremendous amount of effort. The experiments describe serologic analysis on globulin fractions with the removal of large amounts of serologically inert serum proteins. Syphilitic, presumed biologic false-positive and normal human serums were studied under external conditions in which the reaction, temperature and serum volume were controlled. The fractions thus obtained were subjected to serologic analysis, protein concentration and electrophoretic-component distribution. The known biologic false-positive human serums were seen to show a significant increase in total titer. In both syphilitic and biologic false-positive human serums the reactive antibodies were exclusively associated with serum gamma globulin. It was observed that crude protein fractions of human serums inhibited selectively the serologic activity of the globulin fraction derived from biologic false-positive human serums. The inhibitory factor may be completely

removed by absorption on cholesterol crystals. Inhibition was selectively directed toward the flocculation action of the biologic false-positive type, that of the syphilitic type being hardly affected. The inhibition phenomenon was more specific toward antigens of high chemical purity, such as cardiolipin. It was suggested that inhibition results from competition for the antigen between the antibodies of the biologic false-positive type and the inhibitor. The lack of inhibition of the syphilitic type of reaction is ascribed to a greater affinity of these antibodies for the antigen. These observations suggested a method for the preparation of antigens exclusively specific for syphilis. In mixtures of euglobulin fractions of the syphilitic and biologic false-positive types, inhibition was exclusively directed toward the latter. A preliminary survey analysis with the euglobulin-inhibition method was made on about 2000 human sera of which about 900 were of definitely established diagnostic origin. Somewhat inconclusive results obtained in a small proportion of these sera were ascribed to a combination of limiting factors, and appropriate measures have been suggested to eliminate the resulting ambiguities. Further refinements of the present method were suggested, and a final routine method is being worked out. A general summary given by the authors themselves will perhaps provide the best condensed version of this work.

The present series of papers describe the evolutionary development of a method for the serologic differentiation between true and biologic false positive reactions for syphilis. It is based on the inhibitory effect of a heat stable serum protein component on the serologic activity of euglobulin fractions of biologic false positive human sera. Agreement between serologic results and diagnostic data was observed in about 95 per cent of the total number of sera of each group.

It is obviously impractical for the practicing physician to indulge in the details of such reports as the foregoing one-hundred-and-twenty-page series of communications. The extremely brief characterization given herein however should serve to portray the tremendous amount of time and effort expended in the laboratory approach to the problem of false-positive serologic tests for syphilis.

An excellent example of the use of quantitative tests in evaluating treatment methods is reported from Bellevue Hospital.<sup>12</sup> Four different rapid-treatment programs were employed, and serologic follow-up study was carried out for extensive periods, no patient observed for less than a year was included in the report. It appeared that prolonged low-serologic titers following rapid treatment for early syphilis did not as a rule indicate failure of treatment. In late latent syphilis, sharp rises in post-treatment titers indicated the need for further treatment, so long as a gradual trend downward existed, no further treatment seemed necessary. Among patients with neurosyphilis no correlation

was found between the height of the blood reagin titer and the severity of the disease, or between the complement-fixation titers of the blood and spinal fluid.

### *Cardiolipin Antigen*

A distinct refinement in the serodiagnosis of syphilis has been the utilization of cardiolipin antigen in the various serologic tests. This is an essentially chemically pure antigen, which has been found to give more specific results.<sup>13,14</sup> In non-syphilitic cases several large series have been studied with apparently more specific results than the antigens routinely used in well established flocculation or precipitation tests. It is also held to be more sensitive than earlier techniques. The excellent results obtained with cardiolipin-lecithin antigen and the great simplicity of the technic recommended suggest that a single standard test of the blood for syphilis worthy of universal adoption can be developed. A quantitative macroprecipitation test for syphilis, employing purified cardiolipin-lecithin-cholesterol antigen has also been described.<sup>15</sup> Cardiolipin antigens used in complement-fixation and flocculation tests for syphilis may, however, produce positive reactions with blood from presumably nonsyphilitic donors in cases of malaria, infectious mononucleosis, upper respiratory infections and some supposedly nonsyphilitic patients.<sup>17</sup> Nevertheless, in a health-department laboratory employing several of the so-called "verification reactions" and quantitative serologic tests, the cardiolipin antigen technic is regarded as of the greatest dependability.<sup>18</sup>

An example of the excellence of the cardiolipin antigen is afforded by a study of the incidence of false-positive tests for syphilis in sporozoite-induced vivax malaria.<sup>19</sup> Ninety institutional volunteers for the experiment were found to develop false-positive reactions in 57 cases (63.3 per cent). The blood sera were subjected to a battery of seven serodiagnostic tests for syphilis for periods as long as eighteen months. False-positive reactions appeared on the average eight and a third days after the development of parasitemia. In the majority of subjects, the nonspecific test was transitory and of low degree. Positive reactions resulting from individual attacks of malaria persisted for intervals varying from two to ninety-eight days. Some false-positive tests persisting for longer periods were observed when successive relapses supervened before the seropositivity due to a preceding attack had subsided, a maximum of five hundred and seventeen days was encountered in 1 such case. It was noted that the blood Hinton test and a microflocculation test employing a cardiolipin antigen yielded results of high specificity in this study — a striking fact in view of their recognized high sensitivity in the serodiagnosis of syphilis.

## CLINICAL PROBLEMS

By far the largest number of publications on syphilis appearing during the last year have been concerned with therapeutic problems and mainly concern the use of penicillin. It seems advisable therefore to omit the usual subdivisions of this report relating to the clinical phases and treatment of syphilis as separate items, combining them into one main group. Therapy will thus be included with clinical problems and reactions to treatment considered in a separate portion.

Without doubt the greatest single contribution to appear in the literature on syphilis in the past year was a book by Moore.<sup>60</sup> Familiarity with this study seems essential to anyone dealing with syphilis in any of its phases. It should at least be available to the physician who may occasionally encounter this disease. The author has had an unparalleled experience in research, in the study of clinical material, and in directing the largest mass study of syphilis ever undertaken. Participating in the survey were forty-four clinics, including several military installations, numerous United States Public Health Service rapid-treatment centers and many large civilian clinics, mostly university centers. The pharmacology, toxicity and mechanism of action of penicillin are thoroughly covered. The unknown phases of the use of penicillin in syphilotherapy are clearly pointed out, and the difficulties of evaluating this new agent are adequately portrayed. To quote directly, Moore states "Several more years must elapse before reasonably final statements can be made as to its (penicillin's) use even in early syphilis, to say nothing of the various important late manifestations." Moore believes that in the present state of knowledge the most acceptable method of treatment is through the aqueous solution given intramuscularly every two to four hours, which is definitely a hospital procedure. He discusses in detail the absorption-delaying methods of administering penicillin and indicates that penicillin in oil and beeswax presents the only one that thus far has a limited current practical application. Methods of management of the various stages of syphilis are suggested. Treatment courses are outlined not only for early syphilis but also for the latent disease and late active phases such as hepatic, cardiovascular, ocular, congenital and central-nervous-system syphilis. Moore has most adequately summarized all the currently available data regarding the use of penicillin in syphilis, subjected it to critical analysis and interpreted the information with distinct clarity. It is remarkable that so much has been accomplished within so few years after the introduction of penicillin for the treatment of syphilis. Many more years—at least ten—would normally be required, but the intense co-ordination of effort applied to the study of penicillin in the treatment of syphilis during the war has enabled Moore to take seven-league steps in but a few years' time.

## Oral Penicillin

The oral administration of penicillin in the treatment of syphilis should be mentioned only to caution against its use. Experimental work with rabbits and mice infected with syphilis was not encouraging.<sup>61</sup> Limited trials in human subjects have been inconclusive.<sup>62</sup> This mode of administration will be tempting to the general practitioner under many circumstances, but should be strictly prohibited. Little enough is known regarding penicillin by parenteral administration, and oral use can as yet only be condemned.

## Penicillin in Early Syphilis

Stokes<sup>63</sup> has placed penicillin at the top of the list of agents for the treatment of syphilis and believes that it will do away with the heavy metals and arsenic altogether. He believes that arsenotherapy has already been replaced by this modality, since penicillin "acts as an arsphenamine," and that there is still a place for bismuth in the treatment of syphilis but thinks that it may eventually also be displaced. The aqueous solution of penicillin administered under hospitalization at intervals of two or three hours is advocated as the procedure of first choice. Suggested total dosages are 2,400,000 to 6,000,000 units for early syphilis, the maximum amount being used for the secondary stages of the disease. For relapsing early infections Stokes advocates double penicillin dosage given at two-hour intervals. He emphasizes the use of adequate quantities of penicillin for a sufficiently long period as initial therapy rather than the repetition of courses of penicillin.

There is available a report of a study of 8000 patients with early syphilis treated by eleven different treatment schedules at sixteen rapid-treatment centers.<sup>64</sup> The treatment programs employed penicillin in total dosages as small as 300,000 units and upwards to 2,400,000 units alone or combined with arsenoxide or bismuth, or both, with various individual doses and treatment periods, or with arsenoxide alone, or combined with bismuth. The five-day arsenical intravenous-drip method gave the most satisfactory results but was abandoned because of the high reaction rate. Penicillin alone was not satisfactory in doses of less than 2,400,000 units. Smaller amounts of penicillin, however, when combined with arsenoxide and bismuth, gave distinctly higher percentages of satisfactory results. A number of other reports indicate that the dose of 2,400,000 units of penicillin may not be sufficient for early syphilis, certainly in the secondary stage.<sup>65, 66-67</sup> Drastically higher total dosage is advocated in revised treatment schedules for the Army.<sup>68</sup> The tentative dosage for early syphilis was stated to be 6,000,000 to 8,000,000 units in seven and a half days. For relapses or reinfections the maximum amount of penicillin is to be administered with the addition of Mapharsen and bismuth. The Veterans

Administration schedule for the management of syphilis is very much like that of the Army, and it also provides a careful classification of all phases of syphilis with treatment schedules for each stage.<sup>9</sup> This is a satisfactory and practical outline, which could well be followed by anyone treating the disease. The combined use of penicillin with arsenoxide and bismuth is properly described, as well as schedules of post-treatment observation. The management of relapses is adequately covered.

Examples of the untoward results of insufficient therapy and a timely warning regarding various pitfalls that may be encountered in the penicillin therapy of syphilis appeared in these columns some months ago.<sup>10</sup> Particularly timely was the advice regarding the ill advised marriage of patients who have been treated for early syphilis with penicillin, especially those who received their therapy during the earlier days of the use of this drug, when lower dosages were employed.

A study of relapse occurring during or after penicillin therapy for syphilis is decidedly enlightening. Among 730 cases of early syphilis treated with varying dosages of penicillin, 110 relapses were observed, some occurring as late as the sixteenth month after cessation of treatment.<sup>11</sup> Second relapses occurring after retreatment with larger doses were usually seen to occur later than first relapses. Some of the original dosage schedules were soon found inadequate and omitted. In each case relapses were treated with double the original dosage, and for second relapses a total quantity as high as 9,000,000 units was administered. The gradually increasing penicillin totals quoted in the last few references indicate clearly the continued need for study of the problem of treating syphilis with penicillin. It is obvious that the optimum dosage schedules are even yet not determined for early syphilis, in which the overwhelming bulk of study has been concentrated. It should also be clear that still more careful follow-up study must be obtained in penicillin treated patients. Monthly titrated serologic tests for a period of at least a year after complete reversal to a negative test would be a desirable attainment. This is often not possible in private practice, but the physician can at least prevail upon the office patient with early syphilis to return at monthly intervals for prolonged observation with routine serologic and physical examination after penicillin therapy.

Words of caution regarding the possibility of masking early infectious syphilis with the penicillin treatment of gonorrhea continue to appear.<sup>12-14</sup> These warnings are deserving of emphasis. The quick cure of gonorrhea with this drug is indeed a blessing, but patients so treated should certainly be followed for periods of not less than six months to be sure that the delayed development of early syphilis will not go unobserved.

### *Latent Syphilis*

Less attention has been directed to this phase of the disease than any other, especially regarding penicillin therapy. Small groups of patients have been observed after penicillin treatment in varying dosage schedules. In general the response has been at least as satisfactory as that with older methods entailing routine chemotherapy. Some workers still advocate the use of iodides and bismuth or bismuth and arsenoxide. Others recommend a penicillin-arsenoxide-bismuth combination.<sup>15, 16</sup> It may be borne in mind that patients in this phase of syphilis do not require anything like the intensive therapy that is necessary for early syphilis or the late and actively destructive forms of the disease. Nevertheless, caution is indicated to avoid a therapeutic paradox, a few injections of bismuth prior to penicillin treatment will prevent a Herxheimer reaction.

### *Late Syphilis*

One of the less common varieties of visceral syphilis is involvement of the pulmonary structures. Syphilis of the lung is most difficult to diagnose and may not even be detected at autopsy. A report on 4 cases has appeared, with a classification and summary of clinical diagnostic criteria.<sup>17</sup> The disease may occur as acute syphilitic bronchial pneumonia, chronic interstitial syphilitic pneumonia, ulcerative and sclerogummatous lesions and syphilitic bronchiectasis. Roentgenographic examination is said to be the most important factor in the detection of pulmonary syphilis and in the determination of the effect of therapy. The x-ray appearance during the response to treatment is the only means by which pulmonary syphilis can be confirmed during the life of the patient.

Cardiovascular syphilis has received considerably more emphasis. In a study of untreated syphilis in the male Negro it was found that definite cardiovascular abnormality was present in about 40 per cent of subjects in the age group over sixty-five years as compared with about 10 per cent of a control series.<sup>18</sup> The treatment of cardiovascular syphilis with penicillin was approached cautiously after untoward reactions had been observed in the earlier experience with this drug. Subsequent studies indicate that significant reactions from penicillin are uncommon in cardiovascular syphilis.<sup>19</sup> In uncomplicated aortitis, doses of penicillin comparable to those used in other phases of late syphilis have been recommended.<sup>20</sup> It seems advisable nevertheless to administer bismuth therapy in preparation for penicillin in all forms of cardiovascular syphilis. In the more serious types of lesions, such as aortic regurgitation and aneurysm, it is questionable whether penicillin should be introduced.

In connection with cardiovascular syphilis, the possibility that malarial therapy used for

syphilis will produce untoward effects on the heart may be considered. A series of several thousand patients with malaria observed by a competent cardiologist during the recent war did not reveal any cardiac condition that could be specifically attributed to malaria.<sup>78</sup> Any chronic disease, especially one resulting in anemia, may produce tachycardia, premature systoles or a functional systolic murmur, and malaria is no exception. In 50 patients of this large group, who had recurrent malaria and all of whom were studied electrocardiographically, there was no finding that could be considered outside the range of normal variation or of specific import. There were no deaths from acute cardiac disease and no proved cases of chronic cardiac disease in this series, and one would thus expect none from therapy with inoculation malaria.

The treatment of gummatous hepatic syphilis with penicillin has been reported with dramatic alleviation of acute symptoms as well as objective and subjective improvement over an observation period of one and a half to two years.<sup>79</sup>

### *Syphilitic Nephrosis*

A group of 12 cases (0.3 per cent) of renal involvement were found among a large number of patients with secondary syphilis in a period of five years.<sup>80</sup> Ten were classified as nephrosis, and 2 as nephritis. Syphilitic nephrosis is characterized by pronounced albuminuria and cylindruria, with renal-function tests not significantly abnormal. In early syphilitic nephritis there is less albuminuria and more hematuria. The differential diagnosis between syphilitic and nonsyphilitic nephritis may be difficult and can be based only on response to antisyphilitic therapy. All the 12 cases responded satisfactorily to therapy, which consisted of oxophenarsine hydrochloride, oxophenarsine and fever and penicillin alone. Only 1 patient had a Herxheimer reaction. It was suggested that if markedly hemorrhagic nephritis is present, a small initial dosage should be used to avoid a Herxheimer reaction. Syphilitic nephritis should be approached with considerably more caution than the nephrotic disease.

### *Penicillin in Oil and Beeswax*

The disadvantage of penicillin therapy has been the impracticability of three-hourly injections around the clock for all except hospitalized cases. It is obvious that the country as a whole or any one section of it contains insufficient hospital facilities for proper three-hourly administration of rapidly absorbable penicillin solutions. Many attempts have been made to devise means of delaying absorption or excretion of injected penicillin to maintain effective levels in the blood. Of the numerous combinations tested, the most practical is that of calcium penicillin in beeswax and peanut oil, devised by Romansky.<sup>81</sup> The standard preparation maintained therapeutic levels for approximately twenty-four hours after a

single injection containing 300,000 units of amorphous calcium penicillin (in 4.8 per cent beeswax by weight in peanut oil) per cubic centimeter of the emulsion. This mixture is commonly referred to as "POB." The originator of POB has reported clinical observation of 4000 cases of assorted infections treated with this substance, among which 600 were more carefully studied.<sup>82</sup> The results were as satisfactory as those obtained by the multiple injections of penicillin in aqueous solution. The incidence of allergic reactions after intramuscular injection of POB was approximately 5 per cent. The preparation has shown no loss of potency at room temperature for a year's time. There is usually some soreness to pressure at the site of injection but usually no more than that following the use of aqueous penicillin. The formation of sterile foreign-body abscesses has occurred most infrequently. So far, there has been no evidence of the development of paraffinomas. Among the 600 cases studied in this report were 75 cases of early syphilis, which comprised the subject of a separate report.<sup>83</sup> The patients received 2,400,000 units during a period of eight days. Follow-up studies of penicillin blood levels showed penicillin present in the blood for a total period of fourteen days. Lesions became dark-field negative in ten to thirty-six hours, both primary and secondary lesions were healed in three to twelve days. Among 60 cases followed for a sufficient time for proper observation, there were only 2 failures. Subsequent work was undertaken with larger doses of penicillin, and a separate group of patients is being studied with the use of a crystalline penicillin suspended in oil and beeswax.

Moore's<sup>80</sup> text does not give unqualified approval of the use of POB but intimates that its usefulness may prove more satisfactory as time passes. In another communication he sounds more optimistic.<sup>84</sup> In any phase of syphilis Moore advises that the average daily adult dose should be 2 cc (600,000 units), to be given for eight to fifteen days or longer depending on the stage of the infection. For early syphilis a minimum total dose of 4,800,000 to 6,800,000 units of POB is recommended. Other observers have reported a series of 802 patients treated with 4,800,000 units of POB in eight days.<sup>85</sup> An alternate schedule of 300,000 units given twice daily showed no advantage (in percentage of failures or relapses) when compared to the 600,000 units administered in one dose. It was suggested that smaller daily doses if continued for more than eight days might prove more effective. These 802 cases were all early infectious syphilis, and the results were eminently satisfactory, the percentages of failures in the various types of early syphilis were apparently no higher than those in any other type of rapid treatment, including follow-up studies of the cerebrospinal fluid.

A number of variants and improvements on the original POB formula have appeared. There is one

clinical report of the treatment of a small group of patients with various infections with one of these newer preparations that seems entirely satisfactory.<sup>55</sup> Combinations of POB with arsenical and bismuth therapy have also been recommended. In general, the results seem to agree with those obtained by the injection of aqueous injections of penicillin, either alone or in combination with chemotherapy.<sup>57</sup> In the management of syphilis these schedules of ambulatory treatment have a tremendous advantage over the hospitalization requirement entailed by aqueous solution. The co-operation of patients is distinctly better when shorter schedules of seven to ten days are employed. This may not be entirely desirable, since there is still considerable work to be done in establishing the optimal time-dosage relation. These ambulatory schedules will be of the greatest value to practicing physicians, and doubtless many different combinations have been improvised by various persons. When such procedures become standardized and well known, the individual physician will be able to proceed with more confidence in the management of syphilis in office practice. There is one report of the POB treatment of a case of syphilitic nephrosis with a dramatic response.<sup>58</sup>

### Chemotherapy

Reports are still appearing upon the short intensive courses of arsenobismuth therapy that were under investigation at the time penicillin appeared.<sup>59</sup> Large groups of patients were studied, especially at military installations. Intensive therapeutic programs were as short as twenty days in some cases. In general the shorter and more intensive programs were found to be inherently toxic, even under expert medical supervision. In spite of relatively good response, both clinically and serologically, these reactions occurred with such severity as to make the intensive programs unjustifiable in comparison to penicillin or penicillin in addition to chemotherapy. When longer schedules were used (twenty-six weeks), the treatment was in general better tolerated, with fewer reactions and generally satisfactory results. It is obvious that great strides had been made in the improvement of older standard chemotherapy routines. The advent of penicillin has of course changed all this, but combinations of penicillin and chemotherapy, as pointed out above, give even more promise.

Newer drugs are still being studied in the field of chemotherapy.<sup>61</sup> Dichlorophenarsine hydrochloride is one that appears to be eminently satisfactory. It has rapid spirocheticidal action and promotes prompt healing of lesions. There is favorable serologic reversal and reactions for the most part are mild and infrequent. This drug gives promise of being less toxic than arsenoxide products and certainly might be employed with caution as a substitute arsenical for patients exhibiting mild reactions

to other drugs of this group, or in combination with penicillin.

(To be concluded)

perhaps as a result of the combination of uremia and congestive heart failure I have not seen the x-ray films yet, but I am not going to change my diagnosis

DR STANLEY M WYMAN Most of the enlargement of the heart is in the left chamber The definite areas of density described in the lower lung field are probably atelectasis in both bases

DR ISAAC TAYLOR Is there any pulmonary edema?

DR WYMAN I cannot see any The question of the mass in the left kidney I cannot quite corroborate I believe that the spleen is enlarged

DR BECKMAN The kidneys were said to be big, and such enlargement is compatible with embolic nephritis, although I cannot rule out pyelonephritis

DR CASTLEMAN Have you any comment, Dr Scott?

DR THORNTON A SCOTT I agree that the patient may have had a calcific aortic valve, with superimposed bacterial endocarditis

DR SEDGWICK MEAD Were there any splenic infarcts? They are often associated with abdominal pain

DR BECKMAN And cerebral infarcts — to account for the mental confusion

#### CLINICAL DIAGNOSES

Chronic glomerulonephritis, with uremia  
Arteriosclerotic heart disease

#### DR BECKMAN'S DIAGNOSES

Subacute bacterial endocarditis, aortic valve  
Embolic nephritis  
Arteriosclerotic heart disease, with congestive failure  
Aortic stenosis  
Pulmonary edema

#### ANATOMICAL DIAGNOSES

*Subacute bacterial endocarditis, aortic valve*  
*Subacute glomerulonephritis*  
Embolic nephritis  
Renal and splenic infarcts  
Papillary adenoma of left kidney, with necrosis and hemorrhage  
Calcareous aortic stenosis

#### PATHOLOGICAL DISCUSSION

DR CASTLEMAN Autopsy confirmed the diagnosis of subacute bacterial endocarditis located on a previously calcific aortic valve There was moderate interadherence of the aortic cusps, with deposits of calcium there — not the full-blown calcareous stenosis that produces a systolic thrill but enough stenosis to produce a murmur Implanted on this old process were numerous vegetations, 3 to 6 mm in diameter, a smear of which at the time of autopsy showed streptococci

The spleen weighed over 400 gm and contained many small infarcts There were also a few emboli

to the kidneys, but the few small renal infarcts were certainly not enough to produce uremia Occasionally, in cases of subacute bacterial endocarditis, especially in those with uremia, not only embolic nephritis but also a true glomerulonephritis occurs, which is what this patient had Many of the glomeruli showed the crescent formation characteristic of glomerulonephritis There was still another renal lesion In the left kidney was a large mass, 10 cm in diameter, which at autopsy looked like renal-cell carcinoma It was very necrotic and full of purulent material, and microscopical sections showed a benign papillary renal adenoma This may have been a precursor of renal-cell carcinoma, but at autopsy there was no evidence of cancer I am almost certain that the gross hematuria that this patient had probably came from the renal adenoma rather than from the infarcts or the nephritis

There was not much edema of the lungs There was some congestion and some hemorrhage into the alveoli, which one not infrequently sees in uremia The purpura was probably a combination of the uremia and the bacterial endocarditis I am not sure that the lesions were true petechiae

DR WARREN BENNETT As I recall them, I think that they were more like purpura

DR TAYLOR That was our impression

A PHYSICIAN Was the liver normal? Was there any evidence of central congestion or cirrhosis? And how about the gastrointestinal tract?

DR CASTLEMAN The liver was normal There was only an acute erosion in the stomach I believe that the epigastric pain was probably due to the infection and to hemorrhage within the renal adenoma

DR J W ZELLER What did the parathyroid glands show?

DR CASTLEMAN They were normal

A PHYSICIAN Did the post-mortem cultures show anything?

DR CASTLEMAN No

#### CASE 34042

#### PRESENTATION OF CASE

A thirty-two-year-old housewife entered the hospital because of vaginal bleeding of ten months' duration

She had always been in good health The menses had begun at the age of ten and a half, with regular periods every twenty-eight days, lasting three to five days She was delivered uneventfully of her first child at the age of twenty-six Twenty months before admission she became pregnant for a second time Between the third and fourth months she had a two-week episode of vaginal bleeding and was confined to bed The pregnancy continued without further difficulty to a normal delivery Following delivery she had four bleeding episodes, two of which required curettage and several transfusions The tissue removed was said to be normal The

last episode began two weeks before entry and continued with the passage of large clots to the day of admission. There was no pain. No tissue was recognized among the blood clots.

Physical examination was entirely negative, except for slight pallor of the mucous membranes.

The temperature, pulse and respirations were normal, the blood pressure was 120 systolic, 76 diastolic.

Urinalysis revealed a specific gravity of 1.018, a ++ test for albumin and a 0 test for sugar. The hemoglobin was 13.2 gm. The prothrombin time and bleeding and clotting times were normal.

On the third hospital day an operation was performed.

### DIFFERENTIAL DIAGNOSIS

DR. SOMERS STURGIS: We have the history of a completely normal ovulatory function. The patient was delivered of her first child at the age of twenty-six. Twenty months before admission she became pregnant for the second time. Between the third and fourth months she had a two-week episode of vaginal bleeding and was confined to bed. The pregnancy continued without further difficulty to a normal delivery. She may have had a low implantation of the placenta or something of that sort, which was not, however, significant enough to interrupt the pregnancy since a normal delivery followed, and therefore the cause of the bleeding in the third and fourth months probably had little to do with the present chief complaint — the vaginal bleeding that started a month after delivery and ten months before entry. Following delivery — that is, in the last ten months — she had four bleeding episodes, two of which required curettage and several transfusions. That means that she had rather extensive bleeding. The tissue removed was said to be negative — negative for tumor, I assume. The last episode began two weeks before entry and continued with the passage of blood clots to the day of admission. I do not believe that the large clots had any particular significance. Recent work on the menstrual discharge shows that menstrual blood does generally clot inside the uterus and that the clot then becomes digested through enzymatic or fibrinolytic action, and for this reason, menstrual discharge does not generally clot because it has already clotted. If there are large clots it seems to be significant merely of more than usually profuse bleeding so that the clot does not stay in the uterus long enough to be digested. There was no pain. No tissue was recognized among the blood clots. Of course, fetal tissue could have been missed.

Physical examination on admission was entirely negative, except for slight pallor of the mucous membranes. I assume that to mean that examination of the pelvis was negative too. The temperature, pulse and respirations were normal. The blood pressure was normal. The urine was essentially normal, with a small amount of albumin.

Hemoglobin was 13.2 gm. The patient had had enough bleeding to have had two dilatations and curettages and several transfusions, and she had been bleeding, with large clots, for two weeks on entry. Yet she came in with a hemoglobin of 13.2 gm., which I should think indicates that she had had rather good supportive measures in the way of iron in the meantime. The prothrombin, bleeding and clotting times were normal. On the third day an operation was performed.

Essentially this is the story of a thirty-two-year-old para II with a completely normal past history and 2 normal children, the only thing of significance that I can find at all in this story is the fact that there was a great deal of bleeding originating after the second delivery. Other than this I cannot see that there is anything at all to point to any diagnosis, and one is forced to consider all the causes of uterine bleeding in a thirty-two-year-old multipara. I think that one could summarize the causes as obstetric and systemic and those due to benign and malignant tumors.

Because the bleeding originated after delivery, one might consider the obstetric possibilities first. Chorionepithelioma causing post-partum bleeding cannot be excluded. We do not know precisely when the episodes of bleeding occurred in the last ten months. In other words we cannot tell whether she had another pregnancy and a miscarriage, or perhaps a missed abortion, or whether, in spite of the fact that no tissue had been found and the dilatations and curettages were negative, a chorionepithelioma developed from such a miscarriage. I do not believe that we can get any further information on that point and must consider it as a possibility. Again, she may have had a placental polyp from another such miscarriage that could have been missed in two dilatations and curettages. She may have had puerperal sepsis causing pelvic inflammatory disease, which interfered with the function of the ovaries and the regularity of the periods, but I think that one could throw that out on the basis of the negative pelvic examination.

In considering systemic causes, anemia itself certainly was not a factor. There is no indication of hypothyroidism or other systemic disease in this history. Could this amount of bleeding have occurred from disorganization of the endocrine system following delivery? Of course, hyperplasia of the endometrium and episodes of long profuse bleeding are frequent while the patient is establishing her rhythm again following delivery. That might give a "negative" dilatation and curettage and can cause fairly profuse hemorrhage. Again, it is hard from what we are given to rule that out.

Of the benign tumors one thinks first of fibroid. If the pelvic examination was negative, there was not much enlargement of the fundus. Could the patient have had a small submucous fibroid that was involved in the two-week episode of bleeding in the second pregnancy and yet was too small to be felt?

to be felt on pelvic examination? I rather think that the chances are against that possibility, because if a submucous fibroid caused two weeks' bleeding during a pregnancy I should think that it would have been responsible for an abortion of that particular pregnancy. Certainly, the patient did not have a large fibroid or it would have been discovered at curettage. She may have had a benign polyp in the endometrium, and this again could conceivably have been missed by two dilatations and curettages, but it does not seem likely. She may also have had adenomyosis of the uterus, even though the regularity and normality of this history before the present episode seem to discount such a possibility.

Could she have had endometrial cancer? I wonder if a vaginal smear was taken. Of course, if it was negative it would tend to make one think that this was not endometrial cancer, although in our laboratory we have missed the diagnosis in about 20 per cent of the group of cancers of the fundus on vaginal smear. The patient presumably did not have cancer of the cervix, which would have been discovered on pelvic examination.

Briefly, these are some of the common causes of uterine bleeding, and the history does not leave us with very much to go on. I should like to ask if it is known whether the patient had stilbestrol at any time in the period of two weeks' bleeding when she was put to bed during the second known pregnancy. A number of patients have been given massive doses of stilbestrol for threatened miscarriage. I have heard of 2 that had hyperplasia of the endometrium and intensive flowing following normal delivery after stilbestrol treatment during pregnancy. If this patient did not have stilbestrol I am really at a loss to know what to guess as the cause in this case. I am inclined to guess that there might have been a placental polyp or a retained placental fragment due to a miscarriage of a third pregnancy following the second delivery.

DR TRACY B MALLORY: Have you any suggestion, Dr Smith?

DR JUDSON SMITH: Can you date the episodes of bleeding more accurately?

DR JOE V MEIGS: The patient bled during the last two weeks before admission.

DR SMITH: Yes, but what was the relation to her delivery?

DR MEIGS: Ten months after the delivery.

DR SMITH: It was too late for the patient to have retained products of conception. If she had a placental polyp she should have started bleeding long before, and if anybody with any competence did two dilatations and curettages on her he should have got the polyp out. It is a perfectly good history for a chorioepithelioma, and the most important fact has not come out at all and that is whether an Aschheim-Zondek test was performed and whether or not it was positive.

DR MEIGS: The test was not done.

DR SMITH: There have been patients with negative Aschheim-Zondek tests and negative curettage that turned out to have chorioepithelioma. But that is a little bit fantastic.

#### CLINICAL DIAGNOSES

Hyperplastic endometrium

Anovulatory menstruation

#### DR STURGIS'S DIAGNOSIS

Placental polyp

#### ANATOMICAL DIAGNOSIS

*Normal uterus*

#### PATHOLOGICAL DISCUSSION

DR MALLORY: Dr Meigs, do you want to tell us what you found?

DR MEIGS: This patient just bled, that is all. She kept bleeding even though there was absolutely nothing wrong that we could make out. Since she had cervical lacerations and a moderate amount of prolapse the best way to treat her was to do a reconstructive procedure with removal of the uterus.

DR MALLORY: The uterus was perfectly normal. The endometrium was in a proliferative phase. It was not even significantly hyperplastic, so that we have no anatomic explanation of the bleeding.

DR SMITH: I have seen 2 or 3 cases of persistent bleeding after a pregnancy in which no cause was ever found and the only cure was a hysterectomy.

DR MEIGS: The patient bled herself down so that she was miserable, and then somebody curetted her, and then the same thing started over again. She had been bleeding for two weeks and was much upset about it, and operation was the only way to stop the bleeding. I think that she was the kind of patient one sometimes wants to give radium to.

If we read over the case histories on gynecologic rounds in the hospital there is no question that there are many patients who come in with unexplained bleeding, why they bleed, I do not know. Perhaps women ought not to menstruate so often as they do. As soon as a woman comes of age and delivers an egg she is biologically supposed to become pregnant like any animal, and she is supposed to keep pregnant and nurse, and keep pregnant and nurse, until she either cannot have any more children physiologically or she dies. I think that we are bound to have, and that we do have a great many cases of unexplained bleeding. Perhaps we shall never know the answer.

DR MALLORY: Our policy in these exercises is ordinarily to discuss cases in which an anatomic specimen establishes the diagnosis beyond reasonable doubt. It is well worth while occasionally to remind ourselves that the most careful histologic examination may reveal nothing in the face of severe functional disorders.

## POSTGRADUATE LECTURE COURSE — 1948

THE third annual postgraduate lecture course in general medicine, presented by the Massachusetts Medical Society and arranged by the Committee on Postgraduate Education, will be held again this year in Sanders Theater, Harvard University, Cambridge. Beginning on Monday, March 8, at 6:00 p.m., the course will run regularly on Mondays from 6:00 to 9:00 and on Wednesdays from 3:00 to 6:00 through May 5. The course is free to all physicians residing in New England, membership in the Massachusetts Medical Society is not necessary for attendance.

Special features presented for the first time this year will be sessions on cancer diagnosis and treat-

ment — the first two of the course — presided over by Dr. Charles C. Lund and Dr. Ira T. Nathanson, a session on April 26 on convulsive seizures, presented by Dr. Wilder Penfield, of Montreal, and Dr. H. Houston Merritt, of New York City, under the joint chairmanship of Dr. William G. Lennox and Dr. Maxwell E. Macdonald, and a clinical, roentgenologic and pathological session to be presided over by Dr. Merrill C. Sosman on April 12. An outline of the program appears on page xi in this issue of the *Journal*.

This lecture course, an outgrowth of the work of the Committee on Postwar Planning, has met with a universal response. In 1947 over 1200 physicians registered for forty-eight hours of instruction, as President O'Hara pointed out in his address to the Society in May, 1947, the course was the equivalent in hours of instruction of a complete college education for over twenty students. Dr. W. Richard Ohler, chairman of the Committee on Postgraduate Education, was referred to as "president of Sanders College," and Dr. Lewis M. Hurxthal, chairman of the subcommittee in charge of the course, as "dean."

Even greater success is expected for the coming course. As before, return postal cards will be sent to all registered physicians in Massachusetts. Those who wish to register immediately for the course should do so by writing to the Postgraduate Lecture Course Committee, Massachusetts Medical Society, 8 Fenway, Boston.

## MEDICAL CARE FOR VETERANS

IN THE October 11 issue of the *Journal of the American Medical Association* appears a most encouraging report from the National Medical Advisory Board of the American Legion. This board submitted several recommendations, which were adopted by the National Convention of the American Legion at its meeting in New York in August, 1947. In general, it appears that the American Legion is enthusiastic about the improved care to veterans, particularly in hospitals that are now affiliated with medical schools through the deans' committees. The Legion went on record as favoring medical research in all its

phases, and approved of the residency program. It even recommended the extension of this residency program to include outpatient clinics, in the expressed belief that this approach would assure the veteran the best medical care possible.

Those who are familiar with the problem consider the extension of the resident teaching service to the outpatient clinics a vital necessity, and it is encouraging to have a group of lay people recommend the adoption of this plan. In addition, the Legion recommends that an intern service in the hospitals where it is appropriate be adopted, and it is in favor of introducing clinical clerkships in the clinical hospitals, to be under the direction of the resident staff members and the supervision of the deans' committees.

This is another step forward. If these recommendations were adopted, there would be available in Greater Boston a vast amount of material that is not now utilized for teaching, and the use of interns and clinical clerks would do much to lighten the routine of the residents now in training. This would result in even better use of these residents for the actual care of the patient. The Legion concluded its recommendations as follows: "It is recommended to the Congress of the United States that when economy is to be practiced in the nation, it should not be at the expense of the health of the veterans who saved the nation."

The policies of General Bradley and General Hawley established good principles for the care of the disabled veteran and, in the past two years, have produced extraordinarily gratifying results, particularly as they apply to the affiliated hospitals with their resident training programs. It is even more gratifying to learn that these policies and their results have so impressed the committee of the American Legion that the Legion has gone on record as stated above. This is no time to be complacent, however. The good results of these policies will continue only so long as they are in charge of public-spirited and unselfish personnel. The care of war casualties must be maintained on a high level and with the minimum amount of interference from those whose policies might be unduly swayed by political expediency.

## A D A FORECAST

The American Diabetes Association on January 1, 1948, put into publication a new, small journal for the general public. The *A D A Forecast* "is designed to extend the doctor's influence, to save his time and to aid in the control of diabetes and the detection of cases yet undiagnosed."

The annual subscription rate for residents of the United States and Canada is \$2.00 for twelve issues. Subscription blanks may be obtained from doctors and druggists and from the American Diabetes Association, Inc., 1 Nevins Street, Brooklyn 17, New York.

Even with the probability that too much printed matter, in the aggregate, sees the light of day, there is always room for more that conveys a message. This is the case with the *A D A Forecast*, which we welcome for the value it will have to diabetic patients the country over.

## MASSACHUSETTS MEDICAL SOCIETY DEATHS

**BRIGHT** — James C. Bright, M.D., of Fall River, died on November 12. He was in his seventy-fifth year.

Dr. Bright received his degree from Jefferson Medical College of Philadelphia in 1907.

His widow survives.

**COPELAND** — Elmer H. Copeland, M.D., of Northampton, died on December 25. He was in his eighty-seventh year.

Dr. Copeland received his degree from New York Homeopathic Medical College and Flower Hospital in 1893. He was a member of the staff of the Cooley Dickinson Hospital and was formerly a censor, commissioner of trials and vice-president of the Hampshire District Medical Society.

Two daughters, two sons and two grandchildren survive.

**KING** — George C. King, M.D., of Fall River, died on December 21. He was in his sixty-second year.

Dr. King received his degree from Tufts College Medical School in 1909. He was a member of the American Academy of Pediatrics and the New England Pediatric Society and was a fellow of the American Medical Association. He was a member of the Board of Trustees, chief pediatrician and member of the staff of the Truesdale Hospital, as well as a former president of the Fall River Anti-Tuberculosis Society.

His widow, a daughter, three sons, his mother, three brothers, two sisters and two grandchildren survive.

**LORD** — William J. Lord, M.D., of Great Barrington, died on December 16. He was in his forty-first year.

Dr. Lord received his degree from Albany Medical College in 1939. He was an officer in the United States Army Medical Corps in World War II.

His widow, his mother, a daughter and two sons survive.

**REESE** — John A. Reese, M.D., of Attleboro, died on December 10. He was in his sixty-third year.

Dr. Reese received his degree from Tufts College Medical School in 1908. He was chief surgeon of Sturdy Memorial Hospital and was a fellow of the American College of Surgeons and American Medical Association.

His widow, a son and a daughter survive.

## MISCELLANY

### FIFTH ANNUAL TROPICAL MEDICINE AWARD

The fifth annual award of the Richard P. Strong Medal for outstanding service in the field of tropical medicine was made to Dr. Neil P. Macphail, veteran surgeon and sanitarian of the United Fruit Company at Quirigua, Guatemala. It was recently announced. The award was presented at the annual dinner of the American Foundation for Tropical Medicine at the Waldorf Astoria in New York City on January 8.

Dr. Macphail has been active in tropical medicine in Central America since 1907 when he accepted a position as quarantine doctor for the plague ridden port of Belize, British Honduras. In the following year he became medical superintendent of the United Fruit Company's East Coast division of Guatemala, a position he still holds. During the past forty years his efforts in combating yellow fever, cholera, endemic malaria, dysentery, snake bite, night blindness and other tropical maladies have earned for him the nickname "El Amado Medico" (the beloved doctor).

Other recipients of the medal, in addition to Dr. Strong have been Rear Admiral Edward R. Stitt, United States Navy, internationally noted author of basic texts on tropical medicine; Brigadier General George R. Callender, United States Army, a leader on tropical medical administration during World War II; and Dr. Neil H. Fairley, Australian authority on tropical diseases.

### AGING OF TWINS

Columbia University has been awarded a grant of \$31,500 by the Rockefeller Foundation for the investigation of the interaction of hereditary and environmental factors in relation to problems of aging. The grant is a renewal of an original gift made by the Foundation in 1945 to the New York State Psychiatric Institute, a part of the Columbia Presbyterian Medical Center.

To the study the health status and activities of New York State twins over sixty years of age who reside in institutions for the aged are being compared with those of twins outside institutions.

## CORRESPONDENCE

### ANOTHER DISTINGUISHED WOMAN PHYSICIAN

To the Editor: I was very much interested in reading the editorial Madame President in the November 13 issue of the *Journal*.

May I suggest that in addition to laying claim with pride and distinction to being the home of the first woman president of the American Public Health Association, Dr. Martha May Eliot, your great medical center can also lay claim with "pride and distinction" to being the home of the first woman president of the American Gastroenterological Association. Dr. Sara M. Jordan, chief of the Division of Gastroenterology of the Lahey Clinic.

Dr. Jordan was for many years the only woman member of the American Gastroenterological Association and two years ago was elected its first woman president. She furthermore enjoys the distinction of being one of the nation's outstanding woman clinicians, being especially well recognized for her very creditable work in the field of gastroenterology.

RUSSELL S. BOLES, M.D.

Rittenhouse-Plaza, Philadelphia

### CLINIC CONSULTATION SERVICE AT

### JOSEPH H. PRATT DIAGNOSTIC HOSPITAL

To the Editor: We should like to call your attention to the fact that, owing to enlarged facilities, we can now take ambulatory diagnostic patients through our Clinic Consultation Service with a minimum of waiting. On our present appointment schedule a patient's first visit can be planned within a week.

This service is similar in every way to the diagnostic service rendered to patients admitted to the hospital except that the

patients are ambulatory and no benefits are paid for such care under the existing Massachusetts Blue Cross.

Because of the pressure for hospital beds we are anxious to care for patients on an ambulatory basis, and we should appreciate your co-operation in directing as many patients as possible to the ambulatory Clinic Consultation Service rather than having them admitted to the hospital.

Appointments for the Clinic Consultation Service can be made by calling HA 6-5650 Extension 377.

RICHARD T. VIOUERS, Administrator

Joseph H. Pratt Diagnostic Hospital  
30 Bennet Street  
Boston

## BOOK REVIEWS

*R K G Rheocardiography. A method of circulation investigation and diagnosis of circulatory motion.* From the Nerve-Clinic, the Physiological Institute, and the Pharmacological Institute of the University of Vienna. By W. Holzer, K. Polzer, and A. Marko. Translated by Mrs. Emma M. Kreidl. 8, paper 43 pp. with 44 illustrations. Vienna: Wilhelm Mandrich, 1946.

This small booklet, which was published in Vienna in 1945 and translated into crude English by Emma Kreidl in 1946 was issued as the first volume of a collection of books on the application of natural science in physics to medical research.

The rheocardiograph is a device for measuring electrical impedance. When it is connected to the right and left arms of a subject by means of electrocardiographic electrodes, a rhythmic motion that corresponds to the heart beat is registered. The authors claim that this rhythmic registration represents the action of the left ventricle. The rheocardiograms recorded in this booklet closely resemble arterial pulse tracings but lack their details.

Electrical-impedance measurement of the body is not new. Hubert Mann (*Proc. Soc. Exper. Biol. & Med.* 36:670, 1937) states:

When the electrical conductivity of any part of the body is measured by means of an alternating current bridge it is found that this conductivity shows a rhythmic variation synchronous with the pulse. Neybour (*Medical Physics*, Glaser) describes the method with a complete bibliography and refers to the curve as an electrical plethysmogram.

Electrocardiographic records of the left ventricle are dissimilar to the rheocardiogram. An electrocardiogram of the aorta shows a greater similarity to the rheocardiogram as does any large arteriogram.

It is worth while to explore the application of all kinds of new techniques to medical science. Little of value has been shown by such application of rheocardiography as that presented in this book, but whether something more useful will eventually be demonstrated remains for the future to reveal.

## BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

*State Central Case Record Systems and Local Case Registers for Tuberculosis*, 12<sup>th</sup>, cloth, 88 pp. Washington, D. C.: Federal Security Agency, United States Public Health Service, Tuberculosis Control Division, Washington, D. C., 1947.

To be fully effective tuberculosis-control programs must be supported by accurate and complete record systems. This manual has been prepared for the purpose of assisting in establishing uniform state record systems and co-ordinating them with local case registers. The primary objectives of the state system are program management, supervision and evaluation. Local case registers are necessary for case

management and evaluation and definition of local problems. The material presented in this manual is based on extensive field studies, particularly in the states of Kansas and Oregon. The text is divided into a number of sections devoted to the various details of equipping, setting-up and managing state record systems and local registers. The binding is done in the loose-leaf style, not adapted to rugged use. The printing and chart work are excellent. The manual should prove useful to public-health workers interested in tuberculosis work.

*Medical Addenda. Related essays on medicine and the changing order.* Studies of the New York Academy of Medicine Committee on Medicine and the Changing Order. 8°, cloth, 156 pp. New York: The Commonwealth Fund, 1947. \$1.75.

This supplementary volume contains six essays by eminent authorities on special problems related to the general studies of the committee. Dr. James A. Miller writes on "The doctor himself," stressing the fact that the quality of medical service depends primarily on the physician himself. The late Dr. Louis Hamman discusses psychosomatic medicine. The remaining papers are by Miss Mary A. Cannon and Miss Harriett M. Bartlett on medical social work, Winifred W. Arrington on psychiatric social work, Dr. Howard A. Rusk on rehabilitation and convalescence and Dr. Ernst P. Boas on chronic diseases. The publication is excellent in all ways, and the volume should be in all medical and social libraries.

*Health and Rehabilitation through Chest Training.* By Samuel Delano, M.D. 8°, cloth, 142 pp., illustrated. New York: Williams-Frederick Press, 1947. \$2.50.

In this small volume Dr. Delano explains his special system of chest training. The text is divided into three parts, one, physiology of the chest, lungs, diaphragm and breathing, two, special system of chest movements, with directions for their use, three, results of chest training in pathologic conditions. The text is well printed, with a good type on good paper and is well illustrated with good photographs and x-ray plates of the chest. The book should be in all collections on physical medicine.

## NOTICES

### MASSACHUSETTS PUBLIC HEALTH ASSOCIATION

The annual meeting of the Massachusetts Public Health Association will be held on Thursday, January 29, at the Massachusetts Institute of Technology. There will be section meetings at 3:30 p.m. A dinner meeting will be held at 6:00 p.m. in the Campus Room, Massachusetts Institute of Technology Graduate House, the charge will be \$1.75, including tax and tip (reservations must be made by January 26 with Mrs. Elizabeth Caso, Harvard School of Public Health, 55 Shattuck Street, Boston). At the evening meeting at 7:00 p.m. C. Mayhew Derryberry, Ph.D., chief, Office of Health Education, United States Public Health Service, will speak on the subject "Health Education — a Catalyst."

### NATIONAL CONFERENCE ON MEDICAL SERVICE

The National Conference on Medical Service will be held at the Palmer House, Chicago, on Sunday, February 8, the 1948 session being opened by the president of the Conference, Dr. Creighton Barker, of New Haven, Connecticut, at 9:30 a.m. "The Practice of Medicine by Hospitals, Health Departments and Medical Schools" will be discussed by Everett W. Jones, general manager of the *Modern Hospital*, Chicago, and Dr. Lowell S. Goin, of Los Angeles. Dr. L. F. Foster, of Bay City, Michigan, will speak on the topic "Medical Public Relations Begins in the Doctor's Office," and Dr. Thomas P. Murdock, of Meriden, Connecticut, and Janet Geister, of Chicago, on "Nursing Problems in America."

The afternoon will be devoted to panel presentations of the subjects, general practice and specialty boards, to be participated in by Dr. Wingate M. Johnson, of Winston-Salem, North Carolina, Dr. C. F. Wilkinson, of Ann Arbor, Michigan, Dr. Leroy E. Parkins, of Boston, Dr. Paul Titus, of Pittsburgh, and Dr. C. N. H. Long, of New Haven, Connecticut.

### AMERICAN HOSPITAL ASSOCIATION

The American Hospital Association will hold the first in the 1948 series of institutes on hospital-personnel relations at the Henry Grady Hotel, Atlanta, Georgia, on February 23-25. This institute is planned to give assistance and to stimulate planning for improved employee relations, not to train personnel officers. Administrators, assistant administrators and personnel officers will be helped to develop and maintain efficient work forces.

Limited to an enrollment of 75, the institute is planned to utilize the three days fully, and those attending are urged to plan longer stays in Atlanta if they desire to visit local hospital or scenic spots.

### NEW YORK TUBERCULOSIS AND HEALTH ASSOCIATION

The Annual Conference of the New York Tuberculosis and Health Association will be held on Tuesday, March 9, at the Hotel Pennsylvania, New York City. Authorities on tuberculosis, social hygiene and health education will present papers at morning and afternoon sessions. The luncheon meeting will feature an outstanding speaker.

The Tuberculosis Sanatorium Conference of Metropolitan New York will meet simultaneously and will elect officers for the coming year.

### FIFTIETH ANNIVERSARY OF CORNELL UNIVERSITY MEDICAL COLLEGE

Cornell University Medical College celebrates its fiftieth anniversary this year. The Alumni Day, which will be held on March 11 at the College, is an event of special significance to all graduates. The program will include registration in the morning, with luncheon at the Nurses Residence, to be followed by a business meeting and a schedule of rounds and conferences in all departments. Dinner will be served at the Roosevelt Hotel, and dancing will conclude the day.

### INTERNATIONAL COLLEGE OF SURGEONS

The sixth international assembly of the International College of Surgeons will be held in Rome, Italy, at the invitation of the Italian Government, during the week of May 16-23, under the presidency of Professors Raffaele Bastianelli and Raffaele Paolucci, of Rome, and Mario Dogliotti, of Turin. The secretary of the assembly is Professor Giuseppe Bendandi, of Rome. Detailed information may be obtained from Dr. Max Thorek, general secretary, 850 Irving Park Road, Chicago 13. For travel information, application should be made to the All Nations Travel Bureau, 38 S. Dearborn Street, Chicago, the official travel representatives for this assembly.

### NEUROPSYCHIATRIC RESIDENCY AT VETERANS ADMINISTRATION HOSPITAL, LYONS, NEW JERSEY

Openings are available in neuropsychiatric residency at the Veterans Administration Hospital, Lyons, New Jersey.

The program consists of one, two or three years of training with intensive postgraduate teaching in clinical neurology and psychiatry, psychopathology, clinical psychology and related sciences and in neuroanatomy, neurophysiology, neuropathology and neuroendocrinology, as well as experience in female and child outpatient psychiatry and in-hospital training for female patients and feeble-minded children and juvenile delinquents.

The type of instruction, supervision and training is carried out in accordance with the requirements of the American Board of Psychiatry and Neurology.

The residency has been approved by the Council on Medical Education and Hospitals, American Medical Association, and by the American Board of Psychiatry and Neurology.

(Notices concluded on page xvi)

## GRAFTON CONVALESCENT HOME

### A Rest and Convalescent Home for Discriminating People

Located in the hills of New England, Grafton, Massachusetts, 32 miles from Boston, 36 miles from Providence, Rhode Island, and 8 miles from Worcester. Built at a cost of \$200,000. A quiet, homelike atmosphere with elegant furnishings. Excellent care by registered nurses in constant attendance. Best of foods served. Private and semi-private rooms at reasonable rates. Competent physicians on call at all times. Patients may have their own physicians or special nurses, if desired. We can take ambulatory or bed patients, including terminal cancer, all drainage cases, diabetes and other chronic diseases. Inspection and correspondence invited.

Telephone — GRAFTON 2124

MRS. ALICE T. JOHNSON, R.N., Superintendent  
 20 CHESTNUT AVENUE, GRAFTON, MASS.

1000 cc flasks  
500 cc flasks  
125 cc flasks  
for hospitals

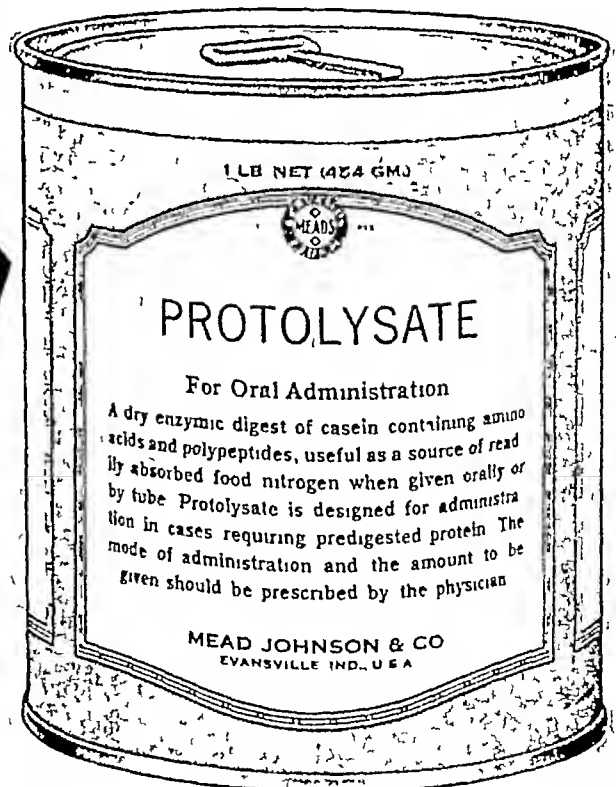

**COUNCIL-ACCEPTED**  
**AMIGEN**  
for parenteral administration  
of amino acids

The function of Amigen and Protolysate is to supply the amino acids essential for nutrition. Both can be given in place of protein when protein cannot be eaten or digested, or in addition to protein when the protein intake is insufficient. Administered in adequate amounts, they prevent wastage of protein, restore previous losses, or build up new body protein.

**COUNCIL-ACCEPTED**  
**PROTOLYSATE**  
for oral and tube feeding  
of amino acids

Like Amigen, Protolysate is an enzymic digest of casein and consists of amino acids and polypeptides. Like Amigen, Protolysate supplies the nitrogen essential for maintenance, repair and growth.

Unlike Amigen, which may be employed both orally and parenterally, Protolysate is designed only for oral use.

1 lb. cans at drug stores

**MEAD JOHNSON & CO., EVANSVILLE 21, INDIANA**

There is no shortage now of AMIGEN for parenteral use. There is no shortage now of PROTOLYSATE for oral use.

## THE CONTROL OF ACUTE RESPIRATORY INFECTIONS IN INDUSTRY\*

GEORGE F. WILKINS, MD†

BOSTON

THE acute respiratory diseases to be discussed today embrace acute infections known as the common cold, pharyngitis, tonsillitis, laryngitis, bronchitis, grippe and influenza. Their relative incidence and severity are essentially the same in the industrial population and in the general population as a whole. They are not occupational diseases. However, in that they are responsible for more illness and loss of production effort than any other single cause, they continue to pose a major problem for industry. Since the majority of these infections are relatively mild in character, result in only a short period of incapacitation and usually do not require medical attention, statistics regarding this class of diseases are quite unreliable. However, it has been estimated that in the United States each employed male loses an average of three days and each employed female an average of four to five days from work annually because of acute respiratory disease.<sup>1</sup> Since there are about 32,000,000 men and 12,000,000 women employed in industry the importance of this problem is evident.<sup>2</sup>

The relative significance of respiratory illness as a factor in absence from work (in excess of seven consecutive days) at the New England Telephone and Telegraph Company is demonstrated by the following data for the five-year period from 1936 to 1940, inclusive, upper respiratory infections were responsible for 37.4 per cent of all sickness absences among men and for 45.1 per cent among women. For the year 1941 alone, respiratory illnesses accounted for more than 50 per cent of all illnesses in excess of seven days in both sexes.

The causative agents in the majority of acute respiratory infections are not known. Presumably they are of viral origin in most cases, but to date only the viruses of influenza A and B have been definitely identified.<sup>3,4</sup> During the winter of 1943-1944, the respiratory illnesses occurring among new recruits at Ft. Bragg during two respiratory epi-

demics were studied. In the first wave, from November 28 to December 24, 80 to 90 per cent of all patients admitted to hospitals for respiratory disease showed increased titers to influenza A. In the second wave, occurring in late December and early January, less than 5 per cent showed increased titers against influenza A. A search was also made for hemolytic-streptococcus infection, and only a few sporadic cases were found. In this second wave more than 90 per cent of the cases were classified as respiratory diseases of unknown etiology, referred to by the Commission on Acute Respiratory Diseases as "ARD." Similar findings have been reported in other studies. Because the viral agent or agents have not yet been identified, prevention of these infections by any procedures of immunization still lies in the future.

Viruses in general have a definite biologic characteristic in which they differ from the pathogenic bacteria. They are obligate intracellular parasites—that is, they require living cells in which to multiply.<sup>5,6</sup> Because of this intracellular existence, they cannot be reached by the ordinary chemotherapeutic or other forms of medication taken up by the blood. It is for this reason that specific therapy of viral infections is for the most part ineffective. There are some exceptions, such as the favorable results obtained with the sulfonamides in trachoma and lymphogranuloma inguinale, and with penicillin in experimental psittacosis.<sup>7</sup> Although the organisms in these conditions are large rickettsia-like viruses, they are nevertheless intracellular. The fact that viruses are obligate parasites also postulates the existence of reservoirs of these agents, otherwise, the diseases they produce would soon pass out of existence. These reservoirs apparently exist in the nasopharynxes of endemic and sporadic cases and perhaps perennially in healthy carriers.<sup>8,9</sup> The principal methods by which these infectious agents are transmitted from one person to another are considered to be four in number as follows:<sup>10</sup> contact—transmission directly as in kissing or indirectly by contaminated hands, instruments or other material

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 20, 1947.  
†Assistant medical director, New England Telephone and Telegraph Company.

objects, droplets\* — transmission directly by projection onto the conjunctivas or skin as in coughing and sneezing, droplet nuclei — transmission indirectly by inhalation of the small residues that result from evaporation of droplets and may remain suspended in the air of enclosed spaces for indefinite periods, and dust — transmission indirectly by inhalation or settling of particles that arise from secondary reservoirs of infection on floors, bed clothing and so forth and remain suspended in air for only short periods

Control of contact and droplet infection must be directed toward individual activity and behavior. Control of droplet nuclei and dust requires attention to the environment. Methods that are applicable to the patient and may be employed in the industrial medical department are considered first.

#### PREVENTION OF SPREAD BY CONTACT

Prevention of transmission by contact comprises three phases: isolation and general measures of personal hygiene, maintenance of individual immunity by means of education, selective individual examination and interviews, vitamins and vitamin supplements and immunization procedures, and dispensary treatment of early cases.

##### *Isolation and Personal Hygiene*

The time-honored advice given to a patient with an acute respiratory infection to "go to bed for twenty-four or forty-eight hours" is undoubtedly of merit. In the absence of fever it is questionable whether or not such a procedure shortens the duration of the infection, but it serves to isolate the patient and thus to prevent spread by contact. Isolation, or two days at home in bed as a mandatory procedure, although ideal from a control point of view, is not always practical in industry. In the absence of profuse nasal secretion, cough or fever, it is probably unnecessary. The observance of general hygienic measures, such as the use of disposable tissues for coughing, sneezing and nose blowing, and cleanliness of the hands, requires no comment.

##### *Maintenance of Individual Immunity*

Individual immunity concerns that rather vague, indefinable but commonly used term "resistance." Sargent and his associates,<sup>9</sup> in a study of 721 otherwise healthy preparatory-school students during the several years of their residence at the institution, found that each boy tended to contract the same number of colds every year, individual boys varying significantly from one another in the number of colds experienced. Sargent et al. attempt to explain this observation by assuming the existence of some "constitutional factor" in the etiology of the common cold in addition to the infecting viral agent. Cannon,

Chase and Wissler<sup>10</sup> believe antibodies to be specifically modified humoral globulins whose formation is dependent on protein intake and reserves. A definite decrease in specific antibody production in animals on a prolonged low-protein diet was observed, followed by a restoration to normal levels after ingestion of adequate amounts of protein hydrolysates or of amino acids. These observations have been shown to be applicable to man as well as animals. It is likely that unknown constitutional factors, diet and numerous other complex variants contribute to the sum total of resistance. Individual resistances are probably as varied as facial configurations or fingerprints. Efforts to maintain a worker in the best possible health — to "keep his resistance high" — therefore seem to have considerable justification, especially since no methods of specific treatment or protective immunization are to date available for the large majority of acute respiratory diseases.

Methods of maintaining individual immunity are as follows:

Education may be accomplished in industry by the use of posters, pamphlets and articles in company organs in which personal hygiene, proper clothing, nutrition, exercise and rest are stressed.

Physical examinations and interviews with chronic absentees or so-called "repeaters" frequently produce favorable results. Chronic states of ill health, such as moderate secondary anemia and focal infections, are often discovered and can be corrected.

Vitamins are mentioned only because of the intense promotion by commercial manufacturers of this supposedly effective method of increasing resistance to infections of all types. To date, no scientific evidence that additional vitamins have any immunologic value in the presence of a diet that supplies the minimal daily requirements of these accessory food factors has been presented. Glickman and his co-workers<sup>11</sup> at the University of Illinois demonstrated that the effects of repeated prolonged exposures to cold were no different in healthy young men on a basal diet with borderline amounts of the water-soluble vitamins from those in subjects fed supplementary vitamins in addition to the basal diet. Bransby et al.,<sup>12</sup> in an experiment with school children aged five to fourteen, in which half were fed supplementary vitamins and half given placebos, concluded that the vitamin supplement had no apparent consistent effect on "growth, strength, endurance, fatigue potential, incidence or severity of clinical conditions, hearing and absenteeism from school." It therefore seems that education regarding proper diet is a much more valuable and much less expensive procedure than providing vitamins in a handy dispensing container for all to help themselves.

\*Since droplets are not appreciably affected by any of the methods of sanitary ventilation, infection transmitted in this manner may be considered to be essentially the same as that by direct contact.

The topic of immunization procedures is included as a comment on cold vaccines, which are also extensively promoted to industrial medical departments. Influenza vaccination, which is of value, is discussed separately below. The lack of effectiveness of the cold vaccines is succinctly stated by Reimann<sup>2</sup> as follows:

The usual commercially prepared cold vaccines contain a mixture of bacteria which have nothing to do with colds, except perhaps as secondary invaders in a small percentage of cases. And even if they did there is no acceptable evidence that vaccine prevents their invasion. Extensive controlled studies by Diehl and others have shown that cold vaccines whether given orally parenterally or as a nasal spray do not prevent colds.

Experience with cold vaccines in the New England Telephone and Telegraph Company was limited to oral vaccine given to 500 employees during the winter of 1939-1940. The results of this trial convinced us that the method is of no value as a preventive measure against colds on any group basis. There are, however, a few persons who swear by oral cold vaccine and who request it routinely each year. Although by no means convinced, we are willing to concede that in an occasional case, such a procedure may have some value. Our present policy is to keep a supply on hand each winter season for anyone who may request it, but its use is not encouraged.

#### *Dispensary Treatment of Early Cases*

The question of treatment of an early case of nasal congestion or "scratchy" throat is intriguing. In this stage of invasion the average person does nothing, waiting until symptoms become more marked and the infection well established before seeking symptomatic relief. In a large metropolitan exchange employing about 1200 girls where there is a consistently high absence rate, penicillin throat spray and sulfathiazole chewing gum were made available during the past winter for use in an attempt to abort early respiratory infections. The spray was employed in a strength of 3000 units per cubic centimeter, the gum contained  $3\frac{1}{4}$  gr (0.25 gm) per portion. Not more than four pieces of gum were dispensed to any patient. The throat was not sprayed more than twice. Psychologically, the effect was excellent, the effect on absence was impossible to assess since the over-all absence rate in the company was approximately 30 per cent lower than that in preceding years — this was a "good season for colds" and as a result there was no basis of comparison. On the basis of scientific evidence there is no justification for such an experiment. However, in large groups of women there are functional factors involved in many absences due or reportedly due to respiratory infections.

#### CONTROL OF AIR-BORNE INFECTION

Transmission of infection by droplet nuclei and dust — the air-borne elements in the spread of

infection — requires control efforts directed at the environment rather than the patient. In hospitals the employment of aseptic technics and isolation precautions have been effective in preventing cross-infections and wound contamination. In factories, offices, military barracks and schools, such methods cannot be adopted. Industry must therefore rely upon air sanitation and sanitary ventilation as the only other available methods of environmental attack. Sanitary ventilation is defined as the disinfection of air by actual ventilation or its equivalent.<sup>3</sup> Air sanitation refers to methods of engineering for the prevention and removal of air contaminants such as dust, bacteria and other noxious agents. Under these two quite similar classifications, the following methods are discussed: simple ventilation, ultraviolet irradiation, germicidal vapors, and oiling of floors (and blankets).

Simple ventilation, as accomplished by open windows, forced air circulation by fans, air conditioning and the like, does have some favorable effect in diluting contaminated air. However, it has been shown that it is not very efficient in reducing the bacterial content of air in an enclosed space.<sup>12</sup>

Ultraviolet irradiation has had extensive trial in military barracks during the past few years. The effects of upper-air and floor irradiation were studied by the Navy Bureau of Medicine and Surgery at Camp Sampson,<sup>14</sup> the barracks being divided into those exposed to high-intensity radiation, low-intensity radiation and controls. During the period of study hospital admissions for respiratory infections were 25 per cent lower in the high-intensity group. There was no significant difference between the low-intensity and control groups.

Dust and lint particles not only are bacteria laden and thus a source of air-borne infection themselves but also, when dispersed into the air by air currents, sweeping, walking and the like, reduce the effectiveness of both ultraviolet irradiation and germicidal vapors.<sup>15</sup> In studies at Fort Bragg, the oiling of floors and bedding (petroleum distillate for floors and mineral oil, and Triton NE, a neutral detergent for bedding) produced from 75 to 90 per cent fewer organisms than those observed in the untreated barracks. However, during the period when the incidence of respiratory infections was high, the large majority of which were "ARD," there was no significant difference in the number of hospital admissions between the treated and the untreated barracks.<sup>15</sup> Employment of ultraviolet irradiation in conjunction with dust-control measures produced no advantage over the use of ultraviolet light alone so far as hospital admissions for respiratory infections were concerned.

In the field of germicidal vapors, the glycols, lactic acid and hypochlorous acid gas have been employed. Lactic acid, although exerting a lethal effect on air-borne bacteria, has an unpleasant odor. Hypochlorous acid gas requires a high relative

humidity and is also corrosive to metals. The glycols depend for their action on their hygroscopic rather than their chemical properties,<sup>15</sup> and to be effective they must be maintained at near saturation levels. Tri-ethylene glycol is superior to propylene glycol in that it does not condense so readily on walls and windows.<sup>17</sup> The glycols require relative humidities of from 40 to 60 per cent for maximum effectiveness. Uniformity of dispersal is also a problem, and the range between effective saturation and fogging is very close. Paints also become sticky after several hours of exposure. In an evaluation of these methods, the Subcommittee for the Evaluation of Methods to Control Air Borne Infections, in its report to the Epidemiology Section of the American Public Health Association in November, 1946, concluded as follows:

The general use of ultraviolet irradiation or disinfectant vapors in schools, barracks and in specialized industrial environments is not justified at the present time. There is great need for further carefully controlled field studies to define mechanisms of the spread of infectious disease among these types of populations.

There is no justification for the indiscriminate use of ultraviolet light or other methods for disinfecting air in homes, offices, or places of public congregation.

An additional fact that should be kept in mind with any method of environmental control as applied to industry, no matter how completely perfected and effective the method may be, is that the worker spends only about a third of his time in his industrial environment. It avails little to work all day in a sanitary atmosphere and then catch cold riding home in a crowded streetcar or later while sitting in a crowded theater.

#### INFLUENZA VACCINATION

Although identification of a virus as the infectious agent in human influenza was made as early as 1933,<sup>18</sup> progress in developing a vaccine for immunization was slow, owing to numerous technical difficulties of culture and concentration. In 1943 the Commission on Influenza undertook extensive trials of vaccination on more than 6000 students in the Army Specialized Training Program in scattered areas of the United States. The vaccine used in this project consisted of a combination of both the PR8 and Weiss strains of virus A and the Lee strain of virus B.<sup>19</sup> As a whole, the incidence of influenza observed among the inoculated was only 31 per cent of that occurring in the controls—a morbidity rate of 2.22 as compared with one of 7.11 per cent.<sup>20</sup> Since that time numerous other studies by members of this commission have indicated the effectiveness of influenza vaccination as an immunizing procedure. From the standpoint of use in industry, some important questions present themselves. These are the hazard of fatal or severe anaphylactic reactions, the amount of absenteeism resulting directly from local or constitutional reactions to the vaccine, the possible development of a

sensitivity to egg protein as the result of vaccination, thus making subsequent vaccinations of the same person a hazardous procedure, and the optimum dosage and mode of administration.

Studies of the periodicity of influenza made it appear likely that an epidemic of influenza A would occur during the winter of 1946-1947.<sup>7</sup> Consequently, the question of vaccination of employees of the Bell Telephone System was considered during the late summer of 1946.

The programs that were adopted varied considerably among the associated companies. In the New England Telephone and Telegraph Company, a very conservative attitude was taken. Vaccination was made available to all employees who had access to the medical offices at Boston and at Providence, Rhode Island. The employees were advised of this fact, but the subject was not promoted. However, to be prepared in the event of a serious outbreak, a program was also established whereby every employee could, if he wished, obtain vaccination from his own physician at company expense. This program was distributed to all supervisory personnel to be held and placed in effect only upon advice from the medical department that influenza was beginning to occur in serious or epidemic proportions. This seemed to be the only practical method to adopt, since employees are scattered throughout the smallest towns and largest cities of Maine, New Hampshire, Vermont, Rhode Island and Massachusetts. Although a mild wave of influenza A appeared in the United States in late March, 1947, New England was not affected except for a few sporadic cases. Consequently, this program was not placed in effect. As of April 26, 1947, the United States Public Health Service reported

There have been no extensive outbreaks of Influenza in New England, the Middle Atlantic States or North Central States areas this season (since January 1947). The largest increases this year over last occurred in the South Atlantic, South Central Areas and in Iowa, Kansas and Colorado. Influenza now is apparently on the decline throughout the United States.

As a result of our conservatism, only 1585 vaccinations were given in the New England Telephone Company. Throughout the Bell Telephone System, however, fourteen other associated companies participated in the program, resulting in a grand total of 120,704 vaccinations accomplished. Of this number, no fatalities and no anaphylactic or other serious reactions were reported. A single dosage of 1 cc of the vaccine given subcutaneously was the method of administration in all cases.

In two companies with the same geographical distribution of personnel, an attempt was made to evaluate the results obtained from vaccines prepared by different methods regarding both antibody levels obtained and the number of reactions encountered.

In Group 1, 3167 subjects were given vaccine prepared by the calcium phosphate precipitation

method, 2853 in Group 2 were given vaccine prepared by the red-cell adsorption method, the so-called "Army type." Questionnaires were distributed to approximately a third of each group at the time of vaccination. Of the total number vaccinated in Group 1, 310, or 10 per cent, returned their questionnaires. In Group 2, 390, or 14 per cent, replied. Of those reporting in Group 1, there were 34 per cent local and 28 per cent general reactions. In Group 2 there were 33 per cent local and 48 per cent general reactions. Antibody titers were done on samples of both groups, and in both there was an effective antibody response, the serum antibody levels being somewhat lower in Group 1 than in Group 2. On the basis of this rather limited study, it appears that the vaccine prepared by the calcium precipitation method produced effective antibody rises with a much lower incidence of constitutional reactions. The effect of vaccination as a cause of absenteeism in the same groups was not significant. Records of day-to-day absence obtained from the operating departments showed no appreciable increase during the vaccination period. The effect of vaccination on absenteeism due to influenza has not been evaluated to date owing to the late occurrence of influenza in 1947, together with other recent disturbances within the industry.

Because a few serious anaphylactic reactions have followed vaccination of persons allergic to egg protein, it is probably wise to withhold vaccination from anyone with such a history. However, the question also arises regarding the possibility of development of such an allergy as a result of influenza vaccination. Plummer,<sup>21</sup> of New York, who has had considerable experience with the influenza-vaccination problem, believes such a development to be extremely unlikely. A review of the literature fails to reveal a report of any such occurrence. It is, however, a problem still to be determined.

Until recently, 1 cc of vaccine given subcutaneously either as a single dose or as two doses of 0.5 cc each, with an interval of seven days, has been accepted as the standard mode of administration.

Recently new interest in this aspect of the problem has been aroused by the report of Van Gelder and his associates<sup>22</sup> on the effectiveness of intradermal vaccination. In their experiments 1953 men were divided into four groups. One group received 1 cc subcutaneously, one received 0.1 cc intradermally, one received 0.1 cc intradermally repeated at the end of two weeks, and the final control group received merthiolate in a 1:40,000 solution intradermally. Serum antibody titers were determined at the time of vaccination, at the end of two weeks and again in one month. The greatest rise in titer was observed in the group receiving a single dosage of 0.1 cc intradermally. Within a month the serum antibody titer had reached a level several times

that produced by a subcutaneous injection of 1.0 cc. More recently, a group of 300 nurses were vaccinated, half of them receiving a subcutaneous injection of 1 cc and the other half receiving 0.1 cc intradermally.<sup>21</sup> Antibody titers were determined on the entire group. In both, effective antibody rises occurred but were found to be slightly higher in the group receiving 1 cc subcutaneously.

Enders<sup>23</sup> has recently given a small series of patients vaccine intradermally diluted in 1.5 parts with physiologic saline solution, 0.1 cc is then given so that the patient receives only 1/50 of 1 cc of this vaccine. In persons with relatively low serum antibody levels prior to vaccination, the antibody response was good, increasing approximately twenty times against virus A and some eight or nine times against virus B. In subjects with high titers prior to vaccination, there was very little increase in the antibody levels.

Although to date there have been no reports to indicate that influenza vaccine of itself produces a sensitivity to egg protein in a person not previously sensitive, such an effect remains a possibility. The intradermal method, therefore, seems to possess the advantage of lessening the hazard of anaphylactic reactions. This method also requires less vaccine and in large groups reduces the expense of vaccination considerably. From the standpoint of vaccination of large groups, however, the subcutaneous method possesses a slight advantage, since it requires less time. If 0.1 cc of vaccine subcutaneously produced an effective antibody rise, this would probably be the optimum dosage and mode of administration.

A final point regarding the advisability of influenza vaccination for the season of 1947-1948 is that the more or less mild outbreaks of the past two winter seasons have served to upset to some extent the future predictions of influenza as based on its past periodicity. It therefore remains uncertain whether an epidemic will or will not occur during the coming winter season. I understand that in the recent outbreak of influenza, definitely identified as due to virus A, vaccination of 10,000 university students at one institution was accomplished. Satisfactory serum antibody levels against virus A were obtained, but no protection was afforded. This suggests the possibility of some strain of virus A other than those incorporated in the current vaccines.\* If true, it will necessitate careful reconsideration of the entire problem. From the standpoint of industry, the question of whether to vaccinate or not to vaccinate is one that will have to be decided by the individual physician charged with the responsibility of the health of his own industrial population. In our company no definite plans for the winter season of 1947-1948 have as yet been formulated.

\*Subsequently identified as the "Rhodes" strain.<sup>24</sup>

## SUMMARY

The problem of acute respiratory diseases in industry is essentially the same as that in the general population

Possible methods of control that may have some application in industry are reviewed

To date, no effective methods of control have been achieved

## THE COURSE OF RHEUMATOID ARTHRITIS IN PATIENTS RECEIVING SIMPLE MEDICAL AND ORTHOPEDIC MEASURES\*

CHARLES L. SHORT, M.D.,† AND WALTER BAUER, M.D.‡

BOSTON

NO METHOD of treatment thus far employed in rheumatoid arthritis can justly be considered "specific"—a term that implies a rapid and complete reversal of subjective and objective manifestations of the disease, whether localized in the skeletal system or in other parts of the body. Such a therapeutic principle, of course, is constantly effective and leaves no doubt of its value in the minds of either patient or physician. Pending the discovery of this long-awaited advance, the treatment of rheumatoid arthritis is necessarily confined to measures believed to be useful but of unproved value. Furthermore, the assessment of newer methods of treatment is always difficult because of the paucity of information concerning the clinical course of rheumatoid arthritis as judged by a large group of patients treated with conservative, generally employed procedures for a number of years. It is the purpose of this report to review briefly such series already described in the literature and to present in detail

the results of a long-term follow-up study of 250 patients receiving simple medical and orthopedic measures.

Whereas almost every description of rheumatoid arthritis includes general statements regarding observations on the course pursued by patients, numerical studies are relatively few.<sup>1-12</sup> In addition, nearly all investigations fail to give sufficient information for use for comparison with other series or for evaluation of new therapeutic measures. In some reports the number of patients studied is obviously too small, and in others the duration of follow-up study is not stated or is limited to months rather than years. With one exception,<sup>12</sup> the cases included have not been subdivided into sex, age, previous duration of the disease, severity of the arthritis and other factors that might influence the results. The degree of improvement has rarely been rigidly defined, patients showing slight improvement being sometimes lumped together with those in remission and subjective gain or increase in functional capacity instead of clear-cut objective changes being utilized as criteria. Some series even contain types of joint disease in addition to rheumatoid arthritis and should of course be eliminated from consideration. A recent, informative article by Steinbrocker<sup>13</sup> presents a further discussion on the

expression of therapeutic results in rheumatoid arthritis

The series reported below is based upon 300 unselected patients with rheumatoid arthritis admitted to the medical wards of the Massachusetts General Hospital between 1930 and 1936. They represent consecutive hospital admissions with the exception that no children under twelve years of age were studied, since they were handled on a separate pediatrics service. The diagnosis in these cases was based on the usual clinical criteria, but all stages of the disease were included. Since some of the patients were in a mild or atypical phase, the absence of either symmetrical phalangeal-joint involvement, x-ray changes or an increased sedimentation rate was not considered a ground for exclusion from the series. Thirty-eight patients with rheumatoid spondylitis (although some authors consider this an independent type of arthritis) were not rejected, especially since the majority had peripheral joints affected in addition to the spine and sacroiliac joints. Other joint conditions, however, such as specific infectious arthritis, gouty arthritis, rheumatic fever and degenerative joint disease, were carefully excluded. In a few patients the passage of time made it clear that the original diagnosis had been erroneous, so that 7 cases were excluded, the number being reduced to 293. Twenty-one patients were also eliminated because they had received special forms of therapy, either vitamin D in massive dosage or gold salts, and 22 because follow-up studies were inadequate. The remainder, 250 in number, form the subject of this report.

The patients were rarely kept in the hospital for more than three or four weeks, for diagnosis and accumulation of clinical and laboratory data and to receive instruction in and a brief trial of therapy. This consisted largely in measures that could be continued at home, including rest periods, analgesics, exercises, application of heat to affected joints, an adequate diet with supplementary vitamins and orthopedic procedures when indicated. Fever therapy, in which we were interested at the time,<sup>14</sup> was given to 52 patients, and 16 received blood transfusions, but neither group did better than the remainder. Removal or treatment of foci of infection was carried out in 75 patients, the rate of improvement approximating that attained in patients in the series not so treated. Thirty-eight patients were rehospitalized for periods of three months or over one or more times in the course of their illness. As might have been expected, they had severer disease, which was not doing well, and ultimate improvement was evidenced in only 29 per cent.

Our original plan for follow-up study was to have each of the patients seen in the clinic at least once or twice a year. But regularity of attendance naturally depended upon their need or willingness to return or, for patients living at a distance or markedly disabled, their ability to make the trip.

Certain patients were thus unavoidably seen at irregular intervals. We were aided in receiving reports about absentees and in getting them back to the clinic by trained follow-up workers and by nurses attached to the departments of public health in Massachusetts and other New England states. The small number who had left New England were kept in touch with by letter, but none were accepted.

as improved unless the evidence was definite and none classified as in remission without examination in our clinic. The duration of observation of the patients after discharge varied from six months to sixteen years, with an average of nine and a half years (Table 1). Thus, 200 patients, or 80 per cent, were followed for more than five years. Because of the length of the follow-up period and because many patients were in the older age groups, 56 died in the course of the study, principally from causes unrelated to the arthritis. The results in such cases are expressed according to the latest examination before death.

The status of our patients, according to the most recent information available up to April, 1947, is expressed in Table 2. They are divided into three

main groups, the base line in all cases being the patients' condition on admission to the hospital. The first group has also been subdivided according to the degree of improvement exhibited. In following the patients, we did not rely upon a set scheme with numerical values assigned to various clinical and laboratory findings.<sup>15, 16</sup> At the time of each observation of the patient, however, subjective and objective

findings pertinent to the clinical course were carefully recorded. Detailed examinations of the articular system, as well as complete general physical examinations, were made at frequent intervals. From 1931 on, sedimentation rates were determined at nearly every return visit to the clinic. Further aid in evaluating the patients' progress was furnished by other laboratory tests and by serial roentgenograms of the joints.

In the group labeled in remission in Table 2, the disease was inactive, the patients asymptomatic

and examination of the joints negative except for residual deformity in a few cases. In all cases, the sedimentation rate as determined by the Rourke-Ernstene<sup>17</sup> method was normal or only slightly increased. The next group, with moderate improvement, showed noteworthy subjective and objective gain but, while approaching this state, could not justly be called in remission. Those judged slightly improved manifested definite objective changes of a favorable nature, and subjective improvement was also present but less marked. Gain in joint function due to conservative or operative orthopedic pro-

cedures was not in itself classified as improvement. The patients of the stationary group were essentially unchanged when last seen, but at least half had previously pursued a fluctuating course, with periods of both exacerbation and improvement. Those with minor variations in symptomatology and joint findings were also included under this designation. The classification "worse" requires little explanation. It includes some patients who were subjectively better and even less disabled, but the disease had progressed as determined by physical

examination and roentgenograms. Conversely, 4 patients who showed marked lessening of activity of the arthritis, but no change in function of the joints or even decreased motion in some, were put into the slightly improved group. Of the patients classified as worse, only 14 per cent were working, 41 per cent were ambulatory, and the remaining 45 per cent (15 per cent of the entire series) were confined to bed or wheel chair.

As mentioned above, there are few reports in the literature on the continued observation for one or more years of comparable series of patients with rheumatoid arthritis. Three may be cited briefly: 77 cases studied by Pemberton and Peirce,<sup>2</sup> 274 by Thompson, Wyatt and Hicks<sup>7</sup> and 253 by Fletcher and Lewis-Faning.<sup>12</sup> In the first, 90.9 per cent of patients showed some degree of improvement, and 22 per cent were considered to be in remission, the figures were 87.2 per cent and 6 per cent, respectively, in the second and 64.4 per cent and 24.6 per cent in the third. There is thus a wide variation in the percentages given for improvement but a general agreement with our own series that a small minority of patients are likely to enter upon a sustained remission. In addition, Sashin, Spanbock and Kling<sup>8</sup> state that 15 per cent of their 120 patients "improved markedly" — a proportion that happens to coincide exactly with those found in remission in our series. Without additional information about differences in prognostic factors, including age and sex of the patients and duration and severity of the arthritis, further discussion of variations in results appears unprofitable. Of more interest, perhaps, are the data obtained from the first follow-up study of the same series of patients, conducted in 1937.<sup>18</sup> At that time the patients suitable for analysis numbered 274. Of these, 145, or 52.9 per cent, showed some degree of improvement, with 16.4 per cent in remission — figures almost exactly the same as those obtained at present but not necessarily representing the same patients. In the past ten years, however, there has been a significant increase in the "worse" group from 18.3 to 34.0 per cent at the expense of those considered stationary, who decreased from 28.8 to 12.8 per cent.

The series presented in this paper was made up of 94 male and 156 female patients. Table 3 demonstrates that the difference in outcome between the two sexes was not significant, although the males did slightly better. At this point, it seemed useful to eliminate any possible influence on these results of the 38 patients with spondylitis, 33 (87 per cent) of whom were males. Table 4 shows no difference of statistical significance between those with and those without spinal involvement, although only 1 patient with spondylitis was considered to be in remission. A similar conclusion is reached in another paper,<sup>19</sup> in which 64.4 per cent of 253 patients with peripheral rheumatoid arthritis showed improvement of some degree compared to 55.8 per cent of 52 patients with

spondylitis. In Table 5, the 38 patients with spondylitis have been excluded from consideration, bringing the number of males down to 61 and that of females to 151. In this table there is a significant difference in favor of males. Since we have been unable to find data in the literature confirming this finding, the results can only be considered suggestive until further evidence is available.

The majority of those expressing an opinion regarding the influence of the patients' age on the

TABLE 5 Results in Male and Female Patients Excluding Those with Spondylitis

course of rheumatoid arthritis believe that older persons tend to do better.<sup>19-21</sup> The one exception encountered has been Schnell,<sup>22</sup> who states that the prognosis is much worse in cases starting after the age of fifty-five. In the present series, no significant differences regarding the age at onset of the disease were found between older and younger patients. When the age on admission to the hospital was taken into consideration, however, patients thirty-nine years of age or younger showed a greater degree of improvement than those forty years or over. The results are presented in Table 6, in which 133 patients in the younger group are compared with 117

TABLE 6 Results in Patients under and over Forty Years of Age on Admission

STATUS OF DISEASE	PATIENTS UNDER 40		PATIENTS OVER 40		DIFFERENCE
	No.	%	No.	%	
Improved:					
In remission	21	0	8	5	19.8 ( $\pm 6.3$ )
Moderately improved	20	3	14	5	
Slightly improved	20	3	18	8	
Stationary		9.8		17.2	
Worse		28.6		41.0	

in the older. Again, only tentative conclusions can be drawn in the absence of corroboration from other series.

The most striking factor apparently affecting prognosis was found to be the duration of the disease. As pointed out in Table 7, nearly three quarters of the 81 patients with duration of arthritis before admission of one year or less showed some degree of improvement, and 37 per cent were in remission. Table 8 demonstrates an even higher percentage of

improvement in patients seen within the first six months, whereas the outcome of those whose onset dated back more than one year was not related to the duration of the disease. That the results are

TABLE 7 Results according to Duration of Arthritis

STATUS OF DISEASE	DURATION BEFORE ADMISSION		DIFFERENCE
	1 YR. OR LESS	MORE THAN 1 YR.	
	No.	%	
Improved	73	9	30.2 ( $\pm 7$ )
In remission	37	0	4.7
Moderately improved	23	3	14.2

Stationary		8.6	14.8
Worse		17.5	41.5

better in patients treated early has frequently been stated without evidence derived from numerical studies.<sup>8, 11, 21, 22-25</sup> In one paper this point has been subjected to careful statistical study in a series of 254 patients, with the conclusion that there is a suggestion that the percentage of success is higher in patients with disease under one year's duration.<sup>12</sup>

TABLE 8 Improvement according to Duration of Arthritis before Admission

DURATION	PATIENTS IMPROVED	
	No.	PERCENTAGE
Six months or less	53	81.0
Twelve to six months	28	60.6
Three to one year	64	45.3
Five to three years	35	34.3
Ten to five years	39	48.7
Over 10 years	31	41.9
Total	250	

Figures presented by Cecil and Archer<sup>1</sup> are comparable to those in Table 8, with 82 per cent of their patients treated in the first six months of their disease either recovered completely or greatly improved. Even more striking results are reported by Steinbrocker<sup>23</sup> in 366 patients with "acute rheumatoid arthritis." Approximately 90 per cent were

TABLE 9 Results according to Type of Involvement

TYPE OF INVOLVEMENT	No. OF PATIENTS	
	No.	PERCENTAGE

Asymmetrical becoming symmetrical	45	40.0
Asymmetrical on admission	17	81.3
Spondylitis	38	44.8
Total	250	

discharged as recovered within three months of admission. Although frequently neglected, these findings should always be taken into consideration in the evaluation of methods of therapy.

The patients with arthritis in the peripheral joints alone were divided into typical symmetrical cases, with involvement of at least one pair of corresponding joints dating back to the period of onset, those who reached this stage some time after the onset and those who were still atypical upon admission. The percentage of improvement in each group, as well as in those with spinal involvement, is shown in Table 9. Although too small in number to warrant conclusions, the asymmetrical group did unusually well, in accordance with previously recorded clinical impressions<sup>20, 26, 27</sup>. Patients without spondylitis were also classified according to the extent of joint involvement (Table 10). There was a marked difference in outcome between those with mild and those with extensive disease. In the same table, a comparable analysis has been made of the degree of activity of the arthritis with both constitutional and articular manifestations included under this

TABLE 10 Results according to Degree of Joint Involvement, Activity of Disease and Total Severity of Process

CHARACTERISTICS OF DISEASE	NO. OF CASES	PATIENTS IMPROVED %
Joint involvement*:		
Mild	75	70.5
Moderate	96	51.2

Moderate	150	51.3
Marked	41	21.8

\*Excluding patients with spondylitis.

heading. Again, the patients with mild activity showed a much higher percentage of improvement than those whose activity was classified as marked. The next heading in the table, "total severity," requires explanation. This was estimated for each patient by two or more observers on the basis of his condition on admission. The factors taken into consideration included the degree of constitutional symptoms and signs, the speed of progression of the disease, the amount of disability, the extent of involvement and the activity of the process. As might be surmised from the results in the two preceding groups, a striking contrast is evident between cases of mild and those of marked total severity. The nearest approach that we have encountered to a similar analysis has been made by Sclater,<sup>28</sup> who divided 388 patients with rheumatoid arthritis into four groups according to the severity of the disease. Milder cases were more numerous among those one year or less in duration, with the opposite found in patients who had suffered from arthritis for four years or more. Although no figures are given, the statement is made that the outlook is very much

worse for patients with disease of marked severity. Similarly, most cases in our series with disease of one year's duration or less and accordingly with a more favorable prognosis were of mild or moderate total severity.

A number of factors that were apparently of no importance in determining the patients' course are listed in Table 11. These included a history of pro-

TABLE 11 Prognostic Factors Apparently not Important in Results

FACTORS	PATIENTS IMPROVED %
Prodromal symptoms	52.5
No prodromal symptoms	53.8

dromal symptoms before onset, an intermittent rather than progressive course before admission and an acute contrasted with a gradual onset. Others were a severe degree of anemia, a family history of rheumatoid arthritis or rheumatic fever and, in women, onset within two years before or after the menopause. There was no significant difference in outcome between those with weight loss of any degree and the remainder. However, out of 27 patients who weighed on admission 79 per cent or less of the average for their age, sex and height, only 26 per cent showed improvement. Four authors<sup>6, 23, 26, 29</sup> agree that poor nutrition evidenced by weight loss is a poor prognostic sign, but our figures fail to corroborate the reported influence of a family history of rheumatoid arthritis,<sup>30</sup> anemia,<sup>28</sup> the menopause,<sup>20</sup> an intermittent course before admission<sup>23</sup> or an insidious in comparison with an acute onset<sup>20, 26</sup>.

When a series like the present one is used in comparison with groups of patients receiving special methods of treatment, the argument may be raised that, although the proportion of patients in each series ultimately showing improvement may be approximately equal, the specially treated group improves much more rapidly. Since our patients were not observed at regular intervals, it is impossible to calculate the rate of improvement in all those finally so recorded. Certain available data, however, may be of assistance. Of 175 patients seen in the clinic one or more times within two years after discharge, 84, or 48.0 per cent, were considered improved, a percentage approximating that finally obtained for the whole series (Table 2). Another approach con-

cerns the 133 patients in the same table who were considered improved at the time of their most recent examination. Improvement was delayed over two years in 30 per cent of these patients and over four years in only 21 per cent, with corresponding figures of 29 per cent and 16 per cent for the 38 patients in remission. It seems fair to assume, then, that in the majority of cases improvement was reasonably rapid but that partial or complete remissions can be looked for in a certain proportion of patients even after several years of discouraging failure to gain.

The variable course of rheumatoid arthritis, marked by periods of exacerbation and improvement at irregular intervals, has often been stressed.<sup>21, 22, 23, 24</sup> Such a course was noted in about half the patients in each group in Table 2 whether finally considered improved, stationary or worse. An additional example of this tendency is given in Table 12, which demonstrates that nearly half the patients who gave promise of early improvement of any degree sooner or later relapsed. A certain number of these, as shown in the table, subsequently improved. The net relapse rate of 34.6 per cent can be compared with a rate of 28 per cent obtained from a combined series in the literature of 768 patients originally showing improvement under gold therapy. In view of the "fluctuant life cycle"<sup>25</sup> of rheumatoid arthritis, "remission" or "arrest" is a more suitable term than cure. If the last is used, it should be prefaced, as in cancer statistics, by the number of years the patients have been observed with the disease in an arrested state. At present, the figure for "five-year cures" in the series is 23 patients, or 9.2 per cent—slightly higher than the 6.3 per cent recently reported for 142 patients given gold therapy.<sup>22</sup>

### DISCUSSION

It is obviously impossible to collect a true control series of untreated patients with rheumatoid arthritis. Nearly every patient with the disease in a recognizable form has received some form of therapy, whether advised by his physician, by an unorthodox practitioner or by a member of his family. We are forced to depend upon groups of patients like those in the present series, who received simple measures generally believed to be helpful or, at times, methods of treatment later proved to be of doubtful value. It is hoped that additional series will be collected and published for comparison with this one and with results attained by special forms of therapy. Certain important principles that should be followed in the selection and analysis of the patients under observation have already been outlined but may be presented here in summary form.

No avoidable form of selection should be used, and, if possible, the patients should represent consecutive admissions to a clinic or hospital. In this way, a wide variety will be under observation, and the series will not be limited to certain types or stages of the disease. The follow-up period should

be spread over years rather than months to allow for the usual relapses and remissions. When the time has come for the evaluation of results, certain factors of prognostic implication should be taken into consideration. These include, at a minimum, the age and sex of the patients, the duration of the disease, the type and extent of involvement and the activity and severity of the process. Improvement should be graded according to degree, with no patients included as improved unless objective articular changes of a favorable nature have been recorded. It is desirable, of course, that a uniform scheme for the evaluation of therapeutic results eventually be adopted.

The results in the present series indicate that about 50 per cent of comparable patients will ultimately

TABLE 12. Relapse Rate of Patients Who Improved within Two Years

STATUS OF DISEASE	No. OF CASES	PERCENTAGE
Improvement within two years	84	—
Later relapses	39	46.5
Complete	31	37.0
Partial	8	9.5
Subsequent improvement	10	—
Relapse on last follow-up examination	29	34.6

imately improve. Since it is planned to keep them under observation as long as possible, this percentage may well change in the course of time. The percentage obtained at present is below "the inevitable 75 per cent improvement"<sup>26</sup> usually mentioned in estimates on the prognosis in rheumatoid arthritis.<sup>26, 27, 28</sup> A milder, strictly ambulatory group might do better, but, as shown in Table 10, the disease was of marked severity in only one sixth of the patients. If the estimated speed of improvement seems less than that in patients treated, for example, with gold, the incidence of relapse in gold-treated patients (75 per cent in one series<sup>29</sup>) must also be taken into consideration. It should finally be made clear that the purpose of this paper is not to claim beneficial results from the conservative routine employed in these patients. Although such methods are generally believed to be helpful, no proof is available that they alter the natural course of the disease.

In addition to presenting the course of the 250 patients to date, an attempt has been made to demonstrate which clinical or laboratory findings are of value in suggesting the outcome. The list studied is by no means exhaustive, and other, more important factors may eventually come to light. With the present evidence, one might assemble a composite patient who would be likely to do well as follows: a man, under forty, with disease of less than a year's duration, of normal or nearly normal weight, with mild joint involvement, preferably asymmetrical, slight activity and mild total severity.

## SUMMARY

Two hundred and fifty unselected patients with rheumatoid arthritis who received simple medical and orthopedic measures have been under observation for an average period of ten years

Over 50 per cent evidenced a definite degree of improvement when last seen, and 15 per cent were considered in remission

Certain factors of prognostic value outlined deserve consideration in the future reporting of therapeutic results

The use of control series of this type seems necessary to determine the effect of nonspecific measures employed in the treatment of rheumatoid arthritis

## ANESTHESIA IN THE SURGICAL TREATMENT OF BRONCHIECTASIS\*

L. H. MOUSEL, M.D.†

WASHINGTON, D. C.

THE anesthesia and operating-room care of patients who are to be treated surgically for bronchiectasis need to be planned and carried out in a simple but logical manner if anesthesia mortality and postoperative complications are to be held to a minimum

Since the advent of penicillin nebulization in the preoperative preparation of these patients, the anesthetic procedures have been simplified considerably. Most patients now come to surgery with comparatively "dry lungs" as compared with those who did not receive the benefit of penicillin therapy by inhalation. It is my belief that bronchoscopy should not be performed immediately before operation, since most of these patients become rather poor

anesthetic subjects. First of all, the patient who is bronchoscoped under topical anesthesia becomes quite disturbed emotionally and is therefore difficult to anesthetize. Bleeding from the tracheobronchial tree is not unusual and certainly complicates the induction and maintenance of anesthesia. Patients in whom bronchoscopy is performed either before or after anesthesia has been established tend to secrete large quantities of mucus from the respiratory tract. It has become a routine procedure in our clinic to spend some time with the patients before operation, explaining as carefully as possible the methods of anesthesia and the supportive measures that will be carried out during the operation to make the procedure a relatively safe one. With such reassurance, patients come to the operating room with a minimum of fear, and the whole anesthetic procedure is simplified.

\*Part of a symposium on bronchiectasis presented at the annual meeting of the Massachusetts Medical Society, Boston, May 21, 1947

†Clinical professor of anesthesiology, George Washington University School of Medicine

Only simple anesthetic practices are carried out. Small amounts of preanesthetic medication are given about two hours before operation. Anesthesia is induced with Pentothal given intravenously in the patient's room to mitigate emotional stress as far as possible. The excitement phase of inhalation anesthesia is eliminated when this method is used.

After Pentothal induction, nitrous oxide and oxygen in a ratio of approximately 75:25 per cent are given for a few minutes to diminish reflex activity of the pharynx and larynx. Ether is then added to the system slowly, and the Pentothal is continued until a sufficient amount of ether has been vaporized to bring the patient into light surgical anesthesia. The trachea is then intubated with a short Magill endotracheal catheter carrying an inflatable cuff. The cuff is inflated with air rather cautiously, just enough pressure to seal the airway completely being used. Two 15-gauge needles are placed in the veins, usually at the ankles. One needle is connected directly to a slow drip of whole blood, and the other is closed with a stilet but kept in place so that it can be used immediately if rapid replacement therapy becomes necessary during severe hemorrhage. The patients are usually placed in the lateral position on the operating table. The Trendelenburg position is not employed because of the increased danger of filling the upper lobe bronchus of the dependent lung with foreign material. The patients are draped in such a manner as to allow the anesthetist a completely unobstructed view of the operative site. The patients are carried in light third-stage, first-plane anesthesia. The respiratory character is watched closely, and the eyes are observed frequently for eyeball movements. If eyeball movement is not apparent the anesthesia is lightened until the eyeballs once more move when the lids are raised. A few minutes before the pleura is entered, a positive pressure equivalent to 5 or 6 mm of mercury is built up in the anesthesia system, this is done to prevent rapid collapse of the lung. The pressure is gradually released after the pleura is opened, and the lung is decompressed slowly. It is my experience that patients who have a slow decompression of the lung rarely develop mediastinal flutter and paradoxical respiration. Positive pressure is rarely required during maintenance. The tidal volume of these patients with one lung completely collapsed has been measured and in almost every case has been equal to or greater than that before anesthesia. When ether and oxygen anesthesia is being used, hilar infiltration is not necessary to lessen the dangers of severe reflex activity during manipulation.

It is necessary to aspirate the tracheobronchial tree quite frequently during operation. A catheter of sufficient length to reach the lowermost portion of the main-stem bronchi is used. In most adult patients ordinary urethral catheters are not of sufficient length, a 45-cm. catheter made from a Wangenstein

stomach tube is used in most cases. Anesthetists in our clinic are required to spend most of their time on their feet watching the operative field and at the same time keeping careful check on the patient's pulse, blood pressure and color, determining the depth and rate of respiration simply by holding the anesthetic bag in the hand. If diaphragmatic movements are observed at all times, tracheobronchial obstruction or mediastinal flutter can be detected several minutes before positive clinical signs are apparent in the character of the blood pressure and pulse and before cyanosis develops. If there is no obstruction and if the mediastinum is stabilized, the diaphragm will be seen to move with smooth, even motions. If diaphragmatic movement suddenly changes from a smooth, even contraction to a more rapid and jerky type the patient has developed either obstruction to the contralateral lung or mediastinal flutter. When this occurs the tracheobronchial tree is aspirated immediately, after which the diaphragm usually resumes its normal rhythmic movements. If the character of the diaphragmatic movements does not become normal after aspiration, a positive pressure equivalent to 4 or 5 mm of mercury is built up in the closed system to raise the mediastinum and stabilize its movements. On rare occasions it is necessary to maintain slightly positive pressure throughout the operation. Controlled respiration is never used because of the danger of gravitating foreign material causing an unrecognized obstruction in one or more of the lobes of the dependent lung. About every half hour during operation the surgeon is asked to stop his procedure for a minute or two while the unoperated lobes are re-expanded. This is done to be sure that bronchi in the uninvolved portion of the lung have not been inadvertently ligated. Re-expansion will also help the surgeon locate imperfectly developed interlobar fissures. The inflatable cuff on the endotracheal tube is decompressed several times during operation to minimize the danger of pressure necrosis.

Whole blood is given from the time the incision is made until the operation has been completed. An attempt is made to estimate as accurately as possible the amount of blood loss in each case. All blood loss is replaced as it occurs. If bleeding is vigorous the blood is allowed to run as fast as possible, and on occasion it is forced into the circulatory system under pressure. If hemorrhage is severe a second bottle of blood is attached to the stiletted 15-gauge needle previously placed in a vein for this purpose. The average patient undergoing lobectomy for bronchiectasis will lose between 1000 and 1500 cc of blood. If citrated blood is readily available and all blood loss is replaced as the loss occurs the operative morbidity and mortality are minimized. After the diseased portion of the lung has been removed the tracheobronchial tree is aspirated as thoroughly as possible. The remaining portion of the lung is

then re-expanded slowly, only enough positive pressure to accomplish the re-expansion being used. After re-expansion the positive pressure in the anesthesia system is reduced until the correct amount of pressure to maintain re-expansion is determined. This pressure is measured on a water manometer and is maintained until all layers of the chest wall have been closed. After the pleura is closed the anesthetist watches the pulse and blood pressure closely, for the amount of pressure required for re-expansion occasionally interferes with circulation once the chest wall has been tightly sutured. If there should be a sudden decrease in blood pressure with a fading pulse volume and increased pulse rate the pressure is reduced.

All anesthetists accepting the responsibility for anesthesia in major thoracic surgery should be able to pass a bronchoscope with the patient in a lateral position so that direct visual aspiration of the tracheobronchial tree can be carried out during operation if necessary. On occasion the removal of large blood clots or other foreign material that cannot be removed by catheter suction is a life-saving measure. After the chest has been closed the patient is turned on his back, water bottles are attached to the drainage tubes, and bronchoscopy is performed to be sure that all foreign material, especially blood clots, has been removed. Our postoperative bronchoscopies are always carried out in a well lighted room. Assistants are required to watch the patient's color and pulse very closely. A vigorous stream of oxygen is passed down the lumen of the bronchoscope during all bronchoscopic procedures to get a rapid diffusion of oxygen into the

patient's lungs. If for any reason the patient develops cyanosis or has a severe change in pulse or blood pressure, the bronchoscope is removed immediately. Deaths during postoperative bronchoscopy have probably been due to suffocation because the tip of the bronchoscope has been wedged into a lower bronchus for a prolonged period, completely obstructing the patient and preventing oxygenation of the remaining lung. Reflex activity probably plays little or no part in the death of these patients.

After bronchoscopy x-ray examination of the chest is performed while the patient is still on the operating table, he is not taken back to his room until the x-ray films have been interpreted. If there is evidence of pulmonary collapse to any degree bronchoscopy is again performed, and the patient is again checked by x-ray examination before being returned to his room. It is realized that many patients would get along well after operation if they were not bronchoscoped immediately postoperatively, however, it is difficult to determine which patients need bronchoscopy and which do not. Occasionally, a large blood clot or a considerable quantity of pus is removed from a patient whose tracheobronchial tree seemed free of foreign material at the end of the operation. If a large blood clot is left in a bronchus the patient may be unable to cough it up postoperatively. Severe atelectasis or death may result. In our patients x-ray examinations are made daily for the first four or five days, and the patients watched closely for evidence of pulmonary collapse. Once the slightest amount of postoperative atelectasis or tracheobronchial obstruction develops bronchoscopic aspiration is indicated.

## LOCALIZED COCCIDIOIDAL OSTEOMYELITIS

TIMOTHY A. LAMPHIER, M.D.\*

BOSTON

**C**OCCIDIOIDOMYCOSIS is a disease produced by the fungus *Coccidioides immitis*, which is present in large concentration in the soil of the San Joaquin Valley, California, and to a lesser degree in neighboring states. In its adult form, it is a spherule of about 50 microns in diameter, which has a doubly refractile capsule. The portal of entry is the respiratory tract or skin. The disease has both primary and secondary phases. Ordinarily, there is a primary pneumonic focus. The nodules produced by the endospores closely resemble those of tuberculosis.

Once allergy is established, reinfection may bring out the disease in its secondary or chronic phase. However, in only a small percentage of cases does the secondary phase develop. Multiplicity of lesions is the general rule, and soft-tissue abscesses, which are common, may extend to underlying bone.

Reports indicate that the prognosis of the disease in its secondary phase is poor, the mortality being over 50 per cent.

Rest and immobilization are requisites to prevent metastatic spread of the disease. As in many of the reported osseous infections, x-ray examination in the case reported below demonstrated a wall outlined about a cavity suggestive of a bony cyst. Removal of a peripheral well advanced bone or joint infection should always be considered, because the possibility that multiple foci will develop is great.

As might be anticipated, the seasonal distribution of initial coccidioidomycosis corresponds to the dusty time of the year. The peak occurs, therefore, in the summer and fall, whereas the ebb is in the few rainy months.

Localized coccidioidal infections of bone are by no means a new entity, having been occasionally reported in the medical literature. The case presented

\*Assistant in anatomy and surgery, Boston University School of Medicine; senior assistant resident, Third Surgical Service, Boston City Hospital.

below is interesting in that the patient had originally been treated as a case of pyogenic hematogenous osteomyelitis at another hospital. It was not until biopsy of the lesion that the underlying disease was demonstrated. When the patient was first seen at this institution, an oval-shaped skin ulcer over the posterior aspect of the right os calcis was present. The center of the ulcer was deeply pitted, and its bed was of a "currant-jelly-like" consistence. This fact, in addition to the exacerbations and remissions that followed combined general and local treatment of the ulcer with penicillin, led to a tentative diagnosis of tuberculosis. Subsequent laboratory studies ruled out this possibility.

It is apparent in the following report that the original chest condition of the patient, diagnosed as "pleurisy with effusion of unknown etiology," was probably a subclinical coccidioid infection.

### CASE REPORT

A 39-year-old private had enlisted in the Army at the age of 22 and enjoyed good health except for frequent head and chest colds during the winter season. At the onset of the war he was assigned to an Infantry division and served in the European Theater. From January to April, 1945 he was a prisoner of war in Germany. During that time he lost 15 pounds in weight, but he had no particular illnesses. In May he was returned to the Zone of the Interior and was given a 60-day furlough which he spent in Phoenix, Arizona. About June 1 he developed a cough, which was accompanied by fever and pain in the right anterior portion of the chest. As his condition became progressively worse, he was admitted to a nearby Army general hospital on June 15.

X-ray examination revealed a small amount of pleural fluid in the medial anterior lower right portion of the chest wall. No etiology for this pathologic state was determined, but after a course of intramuscular penicillin therapy the chest pain ceased, the chest fluid cleared, and the patient became afebrile. At the end of July he was given a 60-day furlough, during the latter part of which pain and swelling developed on the posterior aspect of the right heel without antecedent trauma. On his return to the hospital x-ray films disclosed osteomyelitis of the right os calcis, and a sanatoria was earned out. Cultures revealed a *Staphylococcus aureus*. The foot was immobilized in a plaster boot with the wound packed open. In November when the boot was changed the wound appeared clean without purulent drainage. However, in December further cultures revealed *Staph. aureus*, and he was again placed on a regime of intramuscular penicillin. X-ray films of the os calcis at that time were reported as showing "no further destruction of bone."

In January 1946, at the request of the patient, he was transferred to the Cushing General Hospital. Physical examination revealed an oval-shaped ulcer over the posterior aspect of the right os calcis. The center of the ulcer was deeply pitted, and its bed was made up of soft tissue that was similar to granulation and was described as having a "currant jelly-like" consistence (Fig. 1). The sinus tracts in the base of the ulcer extended down to the os calcis. There was a marked degree of induration about the lesion and the wound was tender when probed.

Examinations of the blood and urine were within normal limits, and the blood serologic findings were negative. Cultures of the draining sinus revealed *Pseudomonas aeruginosa* and a hemolytic *Staph. aureus*.

A ray examination showed no essential change in the appearance of the os calcis. The *Pseudomonas* infection was easily controlled with applications of 1 per cent acetic acid solution, after which penicillin was given intramuscularly (25,000 units every 3 hours) for 3 weeks. In early March because of continued improvement of the ulcerous lesion the patient was considered a candidate for skin grafting, but just before operation the lesion again broke down and drained a thin serous material from which a nonhemolytic staphy-

lococcus and a streptococcus were cultured. As the ulcerous area broke down repeatedly over a period of 6 weeks, guinea pig inoculation with samples of the serous drainage was carried out, and two biopsies of the sinus tract were forwarded to the Pathology Section.

The pathological report in mid-April was as follows:

The sections show loose granulation tissue densely infiltrated with round cells, plasma cells, polymorphonuclear leukocytes and fairly numerous giant cells. The polymorphonuclear leukocytes frequently form packed nodules surrounded by areas of necrosis. Closer examination reveals a number of oval or round bodies, which measure 10 and 20 microns in diameter, have thick refractile capsules and are filled with fine bodies resembling spores. The pathological diagnosis is coccidioid granuloma.

Subsequent coccidioidin skin tests and complement fixation studies confirmed the diagnosis and the fungi were plated out on appropriate culture material.

After consultation with Dr. C. E. Smith of Leland Stanford University, x-ray treatment was instituted but was given up

FIGURE 1 Photograph of Lesion

8 weeks later because of no change in the status of the lesion. In the interim streptomycin sensitivity tests in vitro proved this drug to be of no value.

During June the patient was given potassium iodide, which temporarily decreased the size of the ulcer, but this therapy was discarded 1 month later when the ulcer again broke down and a generalized typical "iodism" rash developed.

After an orthopedic conference it was decided that amputation was the procedure of choice, and the patient was sent to an amputation center where the right extremity was amputated below the knee joint, allowing for a functional stump. The amputation site was revised 2 months later. A follow-up examination 6 months later revealed that the stump had remained well healed. The patient's general condition was excellent at that time.

### SUMMARY

A case of localized coccidioid infection of the os calcis that did not respond to general and local therapy is presented. Amputation of the extremity

was followed by highly satisfactory wound healing without further dissemination

## MEDICAL PROGRESS

### SYPHILIS (Concluded)

G MARSHALL CRAWFORD, M D \*

BROOKLINE, MASSACHUSETTS

#### *Syphilis in Pregnancy*

One of the most favorable situations for the use of penicillin in syphilis seems to be during pregnancy. The antibiotic appears to be especially effective during the gravid state, having almost a dramatic influence. It should certainly replace arsenotherapy without qualification in pregnancy with syphilis. Practically every report dealing with this phase of syphilis is an unqualified endorsement of the use of penicillin.

As in other phases of the disease, numerous schedules have been employed experimentally and the minimum treatment standards are beginning to be established. In general it is agreed that not less than 2,400,000 units of penicillin will be satisfactory<sup>63, 62</sup>. Results have shown that treatment of the mother as late as the seventh month of pregnancy is successful in obviating congenital disease, provided that the infant is viable. Penicillin thus has the advantage over chemotherapy in the treatment of syphilis in pregnancy since it may be given at any stage, even at termination of pregnancy, with at least a possibility of a syphilis-free infant, although early treatment is distinctly advisable. The usual follow-up study of the mother and infant can by no means be neglected. The incidence of Herxheimer reactions in pregnancy is high enough to necessitate relatively small doses during the first twenty-four hours, if the size of the penicillin injections is steadily increased, there is little or no likelihood of a Herxheimer reaction.

Some workers are using a minimum of 4,000,000 units of penicillin for syphilis in pregnancy<sup>63</sup>. With this amount it is believed that nonsyphilitic infants can be obtained regardless of the period of gestation in which penicillin therapy is started. It should be stressed that frequent observation is essential during the prenatal period to detect evidence of serologic or clinical relapse in the mother. Should this occur, a healthy child may still be obtained if retreatment is promptly instituted. A second course of therapy may also be necessary during pregnancy in a few patients who do not show satisfactory clinical or serologic response. Only a careful follow-up study, preferably with titrated serologic determinations, can tell whether a pregnant woman is making satisfactory progress after penicillin therapy during pregnancy. There is some belief that a syphilitic woman who has responded satisfactorily to penicillin therapy during pregnancy and delivered a normal infant need not be retreated during an ensuing pregnancy, if adequate follow-up observation is assured. This entails serologic studies and thorough examination at regular intervals after the original course of penicillin therapy and throughout each subsequent pregnancy. Should the woman then remain free of any evidence of syphilis, she might go through an ensuing pregnancy without treatment and produce a normal infant. If this fact proves to be true over a prolonged period and in a sufficient series of cases, it will have eliminated the necessity of treatment in each succeeding pregnancy in every woman who has ever had syphilis.

There is a report of the study of comparative effects of an aqueous solution of penicillin vs. POB

\*Acting head, Department of Dermatology, Harvard Medical School, acting head, Department of Dermatology, Massachusetts General Hospital

in the treatment of the syphilitic pregnant woman<sup>44</sup> In this comparison only 2,400,000 units of aqueous penicillin was employed, as against 4,800,000 units of POB The over-all results were approximately equivalent in the two series, but one wonders whether equal dosage might have shown an advantage in the use of three-hourly aqueous solution Penicillin therapy for the pregnant woman should be at least that employed in the patient with early syphilis Although a total of 2,400,000 units may be sufficient to protect the fetus, the cure of the mother may require a higher dosage than this, and the 2,400,000-unit quantity should be regarded as an absolute minimum There is no obvious contra-indication to a larger dosage than this, and it should be unhesitatingly recommended Maximal rather than minimal therapy is most certainly desirable for both mother and infant There is some opinion that POB is less effective for symptomatic early syphilis in late pregnancy if the fetus is already infected In this situation better results should be more uniformly obtained by the use of an aqueous solution of penicillin with the woman hospitalized It is obvious that the risk of infection of the fetus would increase in proportion to the infectiousness of early disease in the mother, so that better results should be obtained among mothers with early latent syphilis and a still more satisfactory outcome when the woman has a late infection The same reduction of initial injections should apply whether the pregnant woman is treated with the aqueous solution of penicillin or POB On the first day 150,000 units of POB should be sufficient, this should be doubled on each of the two successive days, and thereafter 600,000 units daily may be continued for a week, providing a total dose of approximately 5,000,000 units

Another study compares the rapid treatment of syphilis in pregnancy by three different methods of approach arsenic and bismuth intensively administered in five to eight days, a penicillin-arsenic-bismuth combination and penicillin alone<sup>45</sup> The results were essentially satisfactory in all three groups, but it is obvious that the intensive arsenic and bismuth therapy should be abandoned and that the addition of arsenic to penicillin during pregnancy in syphilis is superfluous

### *Congenital Syphilis*

There are a number of communications regarding the treatment of all stages of congenital syphilis with penicillin In general the response has been good in earlier cases and satisfactory but much slower in late congenital disease This roughly parallels the course of the acquired form of the disease, as might be expected Interstitial keratitis has been notoriously poor in its response to penicillin, and nearly all observers have seen some cases of interstitial keratitis that were apparently aggravated by penicillin Even the combination of hyper-

pyrexia with penicillin has not provided anything like a uniformly satisfactory response in the treatment of interstitial keratitis

There seems to be uniformity of opinion that penicillin therapy in congenital syphilis is a safe and nontoxic method<sup>46</sup> Herxheimer reactions are as a rule not to be feared even in infants, and large initial doses are preferred<sup>47</sup> When clinical improvement has not been seen, the difficulty was usually attributed to anemia, debility or feeding problems The healing of all types of lesions was rapid in early congenital syphilis, but serologic response was in general slower than that observed in the acquired disease The doses employed have varied from 20,000 to 400,000 units per kilogram of body weight<sup>48</sup> Stokes<sup>49</sup> endorses the latter maximal figure Elapsed time of therapy ranges from seven and a half to fifteen days Negro children appear to have responded better than white<sup>50</sup> Clutton's joints and juvenile paresis have responded less satisfactorily but not so poorly as interstitial keratitis<sup>100</sup> The use of penicillin in osseous congenital syphilis appears to vary in accordance with the time of administration and the age of the patient<sup>101</sup> Doses of penicillin so far employed have temporarily accelerated healing of osseous syphilis only in infants treated during the first three months of life This acceleration occurs principally in osteochondritis and osteomyelitis, simultaneous improvement in periostitis is only of doubtful significance The latter seems to subside slowly after the first three months of life but does so in a more or less spontaneous fashion without much apparent influence from therapy Here again is an obvious indication for the earliest possible diagnosis and the institution of treatment during the first months of life if possible

Combined therapy of congenital syphilis with penicillin and arsenic and bismuth has also been advocated<sup>74</sup> One observer, however, seems to believe that penicillin is not the therapy of choice for congenital disease, regarding it merely as adjuvant therapy<sup>102</sup> The bulk of evidence is certainly against this opinion with the exception of those few types of involvement that have not so far responded too well, such as interstitial keratitis, articular disease, osseous syphilis and juvenile paresis Further study of methods and the various combinations of treatment may change this situation

It is not amiss perennially to call attention to the fact that syphilis in the newborn is prevented by proper therapy of the mother<sup>103</sup> Failure rates are reported as low as 1.6 per cent, even when penicillin therapy is administered as late as the thirty-second week of pregnancy, whereas the best of older methods failed in about 5 per cent of cases The one phase of syphilis that should be the most easily eliminated is congenital disease If all pregnant women were properly checked and treated as

indicated, this type of syphilis could be quickly stamped out

### *Neurosyphilis*

More reports have appeared in the literature regarding syphilis of the central nervous system than any other phase of the disease aside from early infections. The bulk of this material is related to therapy, and especially penicillin treatment.

A most interesting paper describes a study of the blood and spinal-fluid barrier and provides an explanation why positive Wassermann reactions occur in the cerebrospinal fluid of syphilitic infants, even though they show no clinical signs of neurosyphilis.<sup>105</sup> The method used was the administration of standard doses of sodium bromide by mouth, on the sixth day, the concentrations of bromide in the blood and in the spinal fluid were determined and compared, from which a permeability quotient was obtained. Normal and syphilitic infants and adults were examined in this fashion. In 8 newborn infants with moderately positive reactions of the spinal fluid, there were accompanying normal cell counts, total protein and colloidal gold values. These data, which could be obtained in adults who have been treated for neurosyphilis, usually indicate inactivity of a disease that has worn itself out, but this thesis cannot account for the findings in newborn infants. All 8 cases showed a high reagin titer in the blood serum, whereas the spinal fluid gave positive reactions with little or no dilution and the accompanying spinal-fluid tests were normal. This pattern may be explained by passive transfer of reagin from the blood into the spinal fluid.

In 4 infants who received antisymphilitic treatment, the spinal-fluid serologic studies showed an unusually rapid return to normal. This may be explained by assuming that the concentration of therapeutic agent in the cerebrospinal fluid is higher in children than in adults because of a highly permeable barrier between the blood and the spinal fluid. In 22 non-syphilitic infants the average permeability figure was significantly lower than the values listed for normal adults and closely approximated the quotients found for adults with neurosyphilis. This indicates that normal infants have an increased barrier permeability and that a positive cerebrospinal-fluid serologic finding in the absence of clinical evidence of the disease is not diagnostic of neurosyphilis and may be due merely to passive transfer of the reagin from blood to spinal fluid. Infants with no evidence of syphilis other than positive reactions to the serologic tests for syphilis should be followed without treatment to determine their status. Increasing reagin titers obviously indicate active disease and require treatment. This same procedure should be adopted in the therapy of infants with a positive spinal-fluid reaction, provided the cell count and total protein are within normal limits.

Asymptomatic neurosyphilis has been treated by several approaches employing the use of penicillin<sup>60, 74, 106, 107</sup>. From 4,000,000 to 10,000,000 units have been advocated both in single and in multiple courses. Penicillin exerts a favorable influence on the spinal-fluid changes in the following order: cell count, protein content, colloidal gold test and Wassermann reaction. The rapidity and the extent of the drug effect depend as a rule upon the severity of the spinal-fluid disorder before treatment and on the duration of the syphilitic infection. It is suggested that the reappearance of spinal-fluid abnormalities is an indication for re-treatment with fever and penicillin in combination.<sup>108</sup> Therapeutic malaria is still regarded by some observers as the most efficacious treatment for neurosyphilis.<sup>107</sup> The use of penicillin therapy alone in the treatment of neurosyphilis has not yet produced effects equal to those of malaria, but with lengthening experience it seems possible that results with penicillin will approach those of older routines.<sup>108</sup> The greatest effect on symptoms and signs has been observed in the mental aberration, inco-ordination, tremors and speech defects of paresis and in the lightning pains of tabes. There was no improvement in destructive lesions, and the advanced pareses were affected least of all. Another report, also dealing with the use of penicillin, predicates that the drug alone may approach or equal the effectiveness of fever therapy in neurosyphilis.<sup>109</sup> The subjective symptoms of tabes dorsalis were less influenced in this group of cases, but a trial of penicillin by itself was held justified in asymptomatic neurosyphilis, tabes dorsalis and meningovascular syphilis.

Combined hyperpyrexia and penicillin therapy have been used rather extensively, as might be expected. The two may be given concurrently or in succession. In a series of 210 cases there were 100 patients who had been followed for a year or more after treatment.<sup>110</sup> The basic course of therapy consisted of 3,000,000 units of penicillin in conjunction with a short course of fever therapy, but results indicated that this was not the optimum amount of treatment for late symptomatic neurosyphilis. Such findings are in accord with numerous others, who have advised maximum penicillin dosage as high as 10,000,000 units. A combination of penicillin with fever therapy is certainly to be recommended for symptomatic neurosyphilis, and many cases warrant the use of additional chemotherapy as well as penicillin and hyperpyrexia. The advent of penicillin has saved months and years of almost continuous treatment for many cases of neurosyphilis. It not only requires less time but also is safer and at least as efficacious as older methods of chemotherapy. It should certainly not be relied upon alone in cases of parenchymatous neurosyphilis, and a good many years must elapse before

more than tentative schedules of treatment can be relied upon

Army procedure recommends penicillin alone, with 9,000,000 units given over a period of twenty-two days, as an initial course for patients with asymptomatic neurosyphilis, acute syphilitic meningitis, diffuse meningovascular neurosyphilis, gumma of the brain or spinal cord and vascular neurosyphilis.<sup>111</sup> Penicillin in addition to fever therapy is stipulated for general paresis, taboparesis, primary optic atrophy, nerve deafness, syphilitic epilepsy and Erb's spinal spastic paraplegia. No further treatment with arsenic, bismuth or penicillin is given, but if after six months no clinical response is observed, retreatment with malaria and penicillin or with penicillin alone may be tried. A Veterans Administration bulletin on the management of neurosyphilis represents the latest combined opinion of a considerable number of authorities.<sup>112</sup> It is an outline of the most important considerations in the diagnosis and treatment of all types of neurosyphilis, including classification, diagnosis, treatment schedules, reactions, post-treatment observation and management of treatment failures and of relapses. It is a condensed but comprehensive review, and the treatment schedules advocated are in general agreement with the Army program and with other references cited above. The maximum course of penicillin is directed to consist of 9,000,000 units over a period of twenty-two and a half days. Fever produced by malaria is preferred to mechanically induced fever, and its combination with penicillin is advocated in all the visceral forms of neurosyphilis. It is stated that patients should be retreated if the cells and protein of the spinal fluid are definitely abnormal six months after treatment has been completed, or if the cell count and protein show a confirmed rising trend during the post-treatment examination period. When clinical response has been unsatisfactory, the patient may be retreated for this reason alone. Practically all patients who are retreated will receive malaria and penicillin unless individual circumstances preclude these measures.

A communication regarding the combined treatment of neurosyphilis with arsenic, bismuth and penicillin as compared with a group of patients receiving penicillin therapy alone, indicates slightly better results after the combined approach.<sup>113</sup> The difference was not statistically sufficient to warrant the additional risks of this particular combination as contrasted with the safety of penicillin alone. It might be suggested that the danger of arsenotherapy could be eliminated and the benefits of bismuth retained. Some syphilologists have for years believed that in a large percentage of neurosyphilis, bismuth therapy was at least equal in efficacy to trivalent arsenic. The authors of this current report observe that sufficient evidence is at hand to justify the treatment of asymptomatic

neurosyphilis with at least one course, and preferably several courses of penicillin, before resorting to fever therapy.

A pentavalent arsenical, Aldarsone, has been under study for several years in the treatment of neurosyphilis. It is said to have spirocheticidal power distinctly superior to that of tryparsamide and to be less toxic. The latest report concerns 54 patients who received over two thousand injections of Aldarsone.<sup>114</sup> The patients were treated with Aldarsone alone, in combination with other chemotherapy, or by Aldarsone combined with hyperpyrexia. The author concludes that Aldarsone is an arsenical of relatively high therapeutic efficiency and low toxicity that may be used with artificial fever and penicillin to improve the results in symptomatic neurosyphilis. The drug was well tolerated in nearly all cases, but untoward reactions were observed in 4. These consisted of herpes zoster, exfoliative dermatitis, nitritoid crisis and constriction of the visual fields. Although Aldarsone may be superior to tryparsamide in every respect, it is obvious that toxic reactions of considerable gravity may occur. Since penicillin acts so admirably as an improvement over all arsenotherapy, it seems only logical to reserve the Aldarsone as a secondary approach, when other methods of combined treatment have not produced satisfactory results.

Primary syphilitic optic atrophy has long been one of the most discouraging phases of this disease. Even when one eye is affected, it has often been impossible to stop progression and prevent involvement of the opposite eye. Chemotherapy has often apparently hastened the progress of blindness. Hyperpyrexia will sometimes suffice to arrest the optic atrophy, but some patients so treated have developed sudden and irremediable loss of vision. Relatively few cases have been treated since the advent of penicillin, but there is at least some encouragement offered thereby.<sup>115</sup> Stokes<sup>116</sup> advocates 10,000,000 units of penicillin combined with malaria therapy as the treatment of choice for optic atrophy. Vertigo is very rarely the only symptom in cases of central-nervous-system syphilis, but this phenomenon has been reported.<sup>117</sup> In the 2 cases described the presenting symptom resembled in all details that of labyrinthine vertigo. The significance of this was not recognized until neurologic examination and spinal-fluid studies had been done. The vertigo disappeared with antisyphilitic treatment, permitting the conclusion that this isolated symptom was probably due to syphilis.

A study of 300 cases of neurosyphilis treated with malaria indicates that *Plasmodium vivax* is a satisfactory inoculation for 90 per cent of white patients.<sup>117</sup> It was not an adequate method of inducing therapeutic fever for some persons who had previously had malaria, for Negroes or for those from the Mediterranean area and Puerto Rico. These subjects were inoculated with quartan malaria, and all but

1 of the white subjects treated by this form responded satisfactorily, all but 7 of 75 Negroes likewise had a therapeutic response to quartan malaria. In white patients who experience a moderate number of paroxysms after a primary vivax inoculation, but fail to attain a clinically adequate amount of fever, a heterologous strain of vivax may be successful. This work demonstrated the successful use of quartan malaria in those patients who are immune to *P. vivax*. In civilian practice, however, there are often difficulties in maintaining the two strains, unless there is a malaria center within reasonable distance to provide the material for inoculation, this approach is out of the question. The same students of susceptibility to malaria have emphasized the complications that may be encountered during therapeutic malaria.<sup>118</sup> Their report is composed of a separate communication derived from study of the same 300 patients. There were 22 cases of jaundice, all occurring during the malaria therapy. About 35 per cent of the patients received ten daily injections of Mapharsen during their convalescence, but no jaundice developed after the termination of malaria therapy. Twenty-one cases of edema were observed during the treatment. Albuminuria lasting for two days or longer was discovered in 48 of the 300 patients, and microscopical examination in 19 of these 48 cases showed varying degrees of hematuria. Four patients developed acute nephritis for which the malaria therapy was considered to be the direct etiologic factor. Thirteen patients developed respiratory difficulty unaccompanied by pneumonitis, 3 more showed roentgenographic evidence of the latter. Bronchial asthma was found to be markedly aggravated during malarial paroxysms. Exacerbations of tabetic crises and lightning pains were observed in 6 cases. Mental complications appeared in only 5 cases, which is a decidedly low incidence and undoubtedly due to the fact there were relatively few cases of advanced general paresis. It should be obvious that only qualified physicians with proper facilities should attempt to carry out any form of hyperpyrexia, whether malarial or induced by physical means. The material in the series of cases reported was all military personnel comprising comparatively young and healthy persons. A cross-section of neurosyphilis in the general population would reveal many more serious and advanced cases of neurosyphilis distributed among patients of lower vitality. Inmates of a mental institution would be deteriorated still further. It should be obvious that the incidence and severity of complications in civilian practice would therefore be grossly magnified and more dangerous than those reported in this current communication.

#### REACTIONS TO TREATMENT

Toxic reactions of considerable severity continue to be reported from the use of arsenotherapy.

Although penicillin treatment has been remarkably free from severe reactions, a few reports regarding such events have appeared.

#### *Lumbar-Puncture Reactions*

An interesting study of the physiologic and psychologic factors regarding lumbar-puncture reactions has been reported.<sup>119</sup> Of a series of 100 patients, punctures were done with a 16-gauge needle in 50 and with a 22-gauge needle in 50. Five times as many severe reactions occurred with the large needle, and the duration of symptoms was distinctly longer. The incidence of symptoms had no significant relation to the intelligence or emotional stability of the patients. Patients with normal moods seemed to suffer severer headaches than those who were depressed or elated. Hypochondriasis evidently predisposed to a slight increase in complications but did not raise the number of severe reactions. Suggestion appeared to be the psychologic factor of primary importance in the production of symptoms. Knowledge of ill effects in others did enhance anticipatory anxiety and exert a suggestive influence with a significant rise in the number of sequelae. The conclusion was reached that drainage was the most significant factor in the production of symptoms following lumbar puncture, outweighing by far the small contribution of anxiety, hypochondriasis and other emotional elements. The statement is occasionally made that constitutional inadequacy, increased suggestibility and emotional instability play a primary role in the etiology of lumbar-puncture reactions. The communication discussed above does not appear to bear out this opinion. Although many patients dread the procedure and have ill founded fears regarding the consequences, most syphilologists might well agree that the largest percentage of patients having post-puncture reactions are those who fail to follow instructions concerning rest and the avoidance of exertion. Hospitalization or bed rest may not be necessary in the majority of cases, but quiet and the omission of physical stress are of decided value.

#### *Penicillin Reactions*

In addition to the well known Herxheimer reaction, which may occur with penicillin as well as any other antisyphilitic agent, a number of reactions have been described.

The so-called "therapeutic paradox," in which a Herxheimer reaction may cause disastrous results, can usually be avoided by the administration of one fourth or one half of the usual amount as an initial dose and a subsequent increase with each injection. It is of decided importance to prevent the Herxheimer reaction in neurosyphilis, cardiovascular syphilis and all other late visceral disease. There is a distressing report of six severe Herxheimer

reactions following injections of such small doses as 1000 units of penicillin.<sup>120</sup> It is possible to avoid such reactions by the administration of a short course of bismuth prior to institution of penicillin therapy. This prophylactic measure serves just as well before penicillin treatment as when used prior to arsenotherapy and should be borne in mind for all cases of late syphilis. Another report concerns two Herxheimer-like reactions of neurologic character occurring in patients undergoing treatment of neurosyphilis.<sup>121</sup> These reactions were of such alarming proportions as to emphasize the advisability of using bismuth therapy in preparation for the penicillin treatment of neurosyphilis; it may well be considered for both symptomatic and asymptomatic disease.

A phenomenon observed by many is the occurrence of Herxheimer reactions in patients being treated by penicillin for infections other than syphilis.<sup>122</sup> The widespread and often indiscriminate use of penicillin may cause the involution of unrecognized lesions of syphilis and yet be insufficient to cure the disease. This not only can give rise to delayed sequelae and crippling complications but also may serve to sensitize the patient, leading to subsequent untoward reaction if penicillin is used for the treatment of syphilis or other infections. Regardless of the purpose of penicillin therapy, the occurrence of a febrile reaction of the Herxheimer type should provide sufficient cause for suspecting syphilis, even in the absence of serologic or other evidence. Moore<sup>40</sup> reports the incidence of Herxheimer reactions in early syphilis as being between 60 and 70 per cent of penicillin-treated cases.

A comprehensive review of the toxic reactions accompanying penicillin therapy divides them according to the role of penicillin as a direct toxin and primary irritant, as an antigen, as an excitant of therapeutic shock and through indirect action on pathologic processes.<sup>123</sup> Penicillin exerts a negligible action as a direct toxin or primary irritant except after its intrathecal use. With the latter method of administration the reactions may involve convulsions, meningismus or a shock-like state, apparently owing to direct irritative phenomena. There is divided opinion about whether intrathecal administration is warranted because of these reactions. They occur infrequently with the dosage employed intrathecally, but the value of this procedure is not sufficiently established to recommend it for more than experimental use. There is ample evidence that penicillin possesses antigenic and allergenic properties, although the reactions that result are less frequent with purified preparations. Sensitivity may be manifested as immediate or delayed reactions. Immediate reactions usually occur in known penicillin-sensitive patients, although a few persons appear to have a primary sensitivity without previous experience with the drug. Delayed

or acquired sensitization, which may be produced by repeated injections of penicillin, may be of short duration or can persist for years. The allergic symptoms following penicillin are usually benign and are of low incidence and transient nature. Urticarial or angioneurotic edema is by far the most frequent reaction and can usually be controlled by the administration of antihistaminic drugs. Fever and arthralgia may be more distressing features of these reactions and require considerable care. The urticarial phenomenon may occur within a few days after administration but has been observed as long as two to four weeks after termination of penicillin treatment. It is seldom that they persist for more than two weeks, but some have lasted for a month. A less common cutaneous reaction is the so-called "id" type of eruption, which has been observed not only accompanying all known methods of administration but also after topical application. It is often necessary to interrupt the penicillin therapy when this phenomenon appears. A case of agranulocytosis occurring during the course of penicillin therapy has been described.<sup>124</sup> The agranulocytosis occurred in association with a macular eruption, there was a rise in the white-cell count soon after penicillin had been discontinued, suggesting that the agranulocytosis was probably due to penicillin. Exfoliative dermatitis following penicillin therapy has also been described.<sup>125</sup> It was suggested that this reaction was due to some impurity in the penicillin used, since patch tests were positive with the brand of penicillin that had been administered but not with a different make of the drug.

In Romansky's<sup>22</sup> series of 4000 patients treated with POB there was a 5 per cent incidence of reactions, which in most cases consisted of urticarial or angioneurotic edema. The "id" type of eruption also occurred, appearing after each injection in a few patients and subsiding by the next day so that therapy was not interrupted. Occasional local reactions were also observed, usually after subcutaneous administration instead of intramuscular injection. This consists of a large patch of localized edema with erythema and a good deal of tenderness. The same peculiar local reaction has also followed the use of aqueous solutions of penicillin. The antihistaminic substances are not so useful with this phenomenon, which should be treated with the application of cold compresses, since hot packs are distinctly aggravating.

#### *Arsenical Reactions*

Reactions continue to be reported from the use of these drugs, especially after intensive arsenotherapy for syphilis. Among a group of 11 cases, only 1 occurred in the course of routine weekly injections of an arsenical preparation, the remainder appearing during intensive arsenotherapy.<sup>126</sup> Therapy with

2,3-dimercaptopropanol (BAL), pentnucleotide and liver extract, as well as blood transfusions in the severer cases, was followed by recovery in all cases. In another series of 500 cases of syphilis treated with moderate daily doses of Mapharsen over a twenty-day period, there were reactions of sufficient severity to interrupt therapy in 190 patients.<sup>127</sup> The reactions encountered in 24 of these cases required the permanent termination of therapy and included cerebral irritation, jaundice, toxic erythema, agranulocytosis, severe fever, hemorrhagic encephalitis and persistent albuminuria. Renal injury as a result of neoarsphenamine therapy is comparatively rare but has been reported.<sup>128</sup> Clinically, the manifestations were similar to those of nephrosis caused by bichloride of mercury and sulfonamide sensitivity, characterized by degeneration and necrosis of the cells lining the tubules.

The use of BAL in arsenical and other metallic poisonings has brought about a remarkable reduction in the severity of many cases of arsenical dermatitis. A study of 227 patients suggests that the proper administration of BAL will accelerate the recovery of patients with arsenical encephalitis, arsenical dermatitis, agranulocytosis or those who have received a massive overdose of Mapharsen.<sup>129</sup> The maximum dose of BAL that it is possible to administer intramuscularly in man at four-hour intervals is 4 mg per kilogram of body weight. Smaller doses on the order of 2.5 mg per kilogram of body weight are desirable to minimize local pain. With an average unit dose of from 2.5 to 3.0 mg of BAL per kilogram of body weight, it is recommended that from four to six injections be given daily for the first two days, with injections twice a day thereafter until recovery. There were 55 patients with arsenical encephalitis who received BAL, and the over-all mortality was 11 per cent. This is a remarkably low incidence of deaths. Among patients treated within the first few hours after the onset of symptoms, the recovery rate was distinctly higher than that in those in whom BAL therapy was delayed for a day or more. Among 88 patients with arsenical dermatitis, the average time for definite improvement in the patients with severe cases successfully treated was three days, thirteen days being required for from 75 to 90 per cent recovery. Of 11 patients with arsenical agranulocytosis only 1 died. In patients with postarsenical jaundice the BAL perhaps accelerates recovery in but a small proportion. In no case of this series was there a serious systemic toxic reaction due to the BAL, suggesting that the unit dosage and the number of injections could be increased in serious arsenical poisoning. Another communication reviews the history of the development of BAL with particular reference to arsenical dermatitis.<sup>130</sup> Undesirable side-effects of this drug are only minimal features if the dose is held to a figure of 2.5 to 3.0 mg per kilogram

of body weight, but beyond this point the incidence increases rapidly. The side-effects include nausea, vomiting, headache, burning sensation of the lips, mouth, throat and eyes, pain in the teeth, lacrimation and salivation, muscular aches, burning and tingling of the extremities, a feeling of constriction of the throat and chest and elevation of the systolic and diastolic blood pressure. These side-effects are usually at their maximum fifteen to twenty minutes after intramuscular injection of the BAL. All these side-effects, even those observed at the higher dosage levels, have so far been temporary. Barbiturates have been recommended as an antidote for the severest side-effects of BAL. This agent has proved of great practical value in preventing and in counteracting many other toxic effects of different arsenicals and of mercury. Its action against many other metallic and nonmetallic poisons is not proved and requires further study. It is most unfortunate that this exceedingly useful antidote to arsenic poisoning was not discovered about thirty years ago when arsenotherapy began to come into general use. It would have minimized many severe reactions and prevented a great many deaths.

\* \* \*

A few brief statements regarding penicillin might adequately conclude this progress report, so thoroughly has this remarkable antibiotic entrenched itself in the management of syphilis. Unfortunately, the disease has increased in the early post-war years, and a more potent antisiphilitic agent, as well as more effective control measures, is welcome. Although only rather general conclusions are as yet warranted with but a few years to study penicillin therapy for syphilis, giant strides have been taken. Penicillin is at least accepted as distinctly superior to any previously used antisiphilitic agent and is the least toxic. There is much to be learned regarding the antibiotic itself, as well as such factors as time-dose relation, effectiveness of the several penicillin species, role of impurities, prolongation of action and so forth.

The problems of resistance, relapse, reinfection, immunity and false-positive serologic reactions remain unaffected. There is at present no known true resistant strain of *Treponema pallidum* to counteract the effectiveness of penicillin, and it is to be hoped that even more effective commercial preparations will become available. No remarkably superior results have been obtained with penicillin as compared to the more effective chemotherapy regimes, but the relative freedom from reactions and saving in treatment time are invaluable attributes of penicillin. Its effectiveness in early syphilis is directly proportional to the speed of diagnosis and institution of therapy, although results in the secondary stage of syphilis still leave much to be desired. Beyond early disease, only neurosyphilis

has received much attention with the use of penicillin. Here its value is also great, but opinion is still divided regarding methods of approach. The ultimate results in all phases of syphilis cannot be determined for many years, and neurosyphilis may well be the last type deciphered.

In the pregnant syphilitic woman is seen perhaps the most amazing and convincingly demonstrated effectiveness of penicillin. This agent has proved its value in both the prevention and the cure of infection in the fetus when given late in pregnancy. There is even the remarkable prospect that subsequent pregnancies may not require retreatment.

Treatment programs for all stages of syphilis need much more study before optimal schedules can be outlined with general agreement. Combinations of penicillin and other antisyphilitic agents may finally prove the most desirable. Surety of diagnosis before institution of therapy and employment of fully adequate quantities of agents are of the same vital importance as in the past. Hospitalization of penicillin-treated patients is impractical for all but a few, and ambulatory-therapy plans are receiving due attention. It is to be hoped that the oil and wax preparations are at least a first step toward that end.

Evans and Dee, which appeared in the January 1 issue of the *Journal*, "0.6 gm." should be changed to read "0.06 gm."

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

### Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

BENJAMIN CASTLEMAN, M.D., *Associate Editor*

EDITH E. PARRIS, *Assistant Editor*

#### CASE 34051

##### PRESENTATION OF CASE

A sixty-six-year-old man, a millinery worker, entered the hospital for the first time complaining of shortness of breath.

One year before entry he first noted moderate exertional dyspnea. Ten days before entry he experienced an attack of epigastric discomfort, which was relieved somewhat by belching but which persisted and gradually became worse. One week before entry he experienced severe distressing dyspnea on retiring, with associated epigastric discomfort radiating over the chest. Subsequent to that episode he was anorexic and in varying degrees of distress, he could not lie down without severe dyspnea, and he developed a hacking cough productive of white sputum. The persistence of these symptoms led to admission to the hospital.

The past history included syphilis twenty years previously, apparently adequately treated, a blood test ten years later was allegedly negative. The patient denied a history and symptoms of diabetes, rheumatic fever or hypertension, and reported no previous dyspnea or chest pain.

Physical examination revealed a thin, dyspneic man with moderate distention of the neck veins. The heart was enlarged to the left by percussion, and the sounds were distant but regular, without friction rub or gallop rhythm. The pulmonic second sound was louder than the aortic second, and there was a Grade I systolic murmur heard in the left fifth interspace. Abdominal examination was negative.

The temperature was 99.4°F, the pulse 100, and the respirations 25. The blood pressure was 150 systolic, 90 diastolic.

Urinalysis was negative except for a +++ test for albumin and 2 to 4 red cells per high-power field and occasional granular casts in the sediment. The white-cell count varied from 11,000 on admission to 24,000 four days later. Repeated guaiac tests on the stools were negative. Blood chemical studies were not remarkable. An electrocardiogram demonstrated left bundle-branch block but no definite myocardial infarct.

On the third hospital day, while on the bedpan, the patient developed lower abdominal pain, which later radiated to the midepigastrium and resulted in moderate dyspnea. Nitroglycerin was given but gave no relief. On the next day he vomited some undigested food and later felt better. On the following day he was noted to have a distended abdomen with high-pitched peristalsis and reported complete obstipation since the onset of pain (forty-eight hours previously). A film of the abdomen at that time showed a nondilated, gas-filled large bowel and loops of small bowel, a glove specimen of the stool gave a ++ guaiac test. Enemas were nonproductive, and proctoscopy to 18 cm showed no mucosal abnormality. A Miller-Abbott tube was inserted, and the patient passed gas by rectum. A barium enema showed narrowing and spasm in the sigmoid, with diverticula, but was otherwise normal. The abdominal symptoms and distention improved, formed stools were passed by rectum, and the Miller-Abbott tube was removed.

On the twenty-second hospital day the patient had another episode of abdominal pain, with radiation to the right subscapular region, tenderness to palpation, most marked in the right upper quadrant, slight spasm in this region and diminished peristalsis. A questionable mass was palpated in the right upper quadrant on the following day. The serum amylase and van den Bergh determinations were normal. Tenderness later migrated to the right costovertebral angle, but x-ray films demonstrated clear renal and psoas shadows. On the thirty-first hospital day he suddenly developed a right hemiplegia and became disoriented and incoherent. A lumbar puncture showed clear, colorless fluid, with a spinal-fluid pressure equivalent to 145 mm of water and with a few fresh erythrocytes. Labored, wet, wheezing respirations were helped temporarily with Aminophylline. He became incontinent of feces and urine, Cheyne-Stokes respirations developed, and he died twenty-four hours later.

##### DIFFERENTIAL DIAGNOSIS

DR. DANA L. FARNSWORTH: May we see the x-ray films?

DR. STANLEY M. WYMAN: The film of the chest shows a slightly enlarged heart, without characteristic configuration. There is hazy density throughout both lung fields, most marked in the central portions and extending out to the central two thirds of the lung field. The extreme periphery in each lung is relatively clear. There is fluid in the left costophrenic angle in the pleural space.

A barium enema shows an area of narrowing and spasm in the midsigmoid with several diverticula. The examination was not continued throughout the colon. Subsequent films show the passage of a Miller-Abbott tube down into the jejunum. There is no marked distention or evidence of obstruction. One film shows several loops of gas-filled small

bowel, and these loops of small bowel are at the upper limits of normal in diameter. I can see no unusual soft-tissue masses or areas of calcification. The second barium enema demonstrates the same finding essentially. In addition, however, the proximal portion of the colon is fairly well visualized and shows no intrinsic disease. One film from the Grabam test shows dye in the gall bladder, which has a normal contour.

Dr FARNSWORTH: The presenting symptom of dyspnea suggests that the patient had heart disease, though this could have been due to pulmonary involvement alone. In chemical pneumonitis, particularly in beryllium poisoning, dyspnea may be the presenting and most disabling symptom. The occupation of the patient rules out this and probably most related possibilities. The acute episode ten days before entry is the one that focuses attention on the heart.

We are accustomed to thinking of severe substernal pain with or without radiation as the cardinal sign of a myocardial infarction. Actually this is the most important and frequent symptom, but dyspnea is probably the next most common symptom and may replace pain entirely. In many cases there may be a merging of the symptoms in such a manner that the patient interprets considerable dull pain as shortness of breath, and only close questioning will distinguish the two. The heart seems to have been beginning to decompensate because orthopnea developed. Shortness of breath is said to be more marked in the recumbent position than in the upright because blood flow through the heart is about 25 per cent greater in the former position; the lungs are more engorged, there is less room for breathing and free heart action with the diaphragm somewhat elevated, and the respiratory center is acted on directly by the stasis of venous blood. The balance in this case was very delicate, and the hacking cough and white sputum suggest pulmonary edema. The absence of hemoptysis makes pulmonary infarct less likely.

The past history is not of much help. The patient could readily have had hypertension for several years without being aware of it whether he had seen a doctor or not. I do not believe that syphilis had anything to do with the present clinical picture.

The physical examination throws further suspicion on the circulatory system—a fundamental cause of the trouble. The distended neck veins indicate backing up from the right auricle, the enlargement being consistent with a moderate hypertension of several years' standing, and the fact that the pulmonary second sound was greater than the aortic is consistent with beginning heart failure. The moderate degree of fever and the elevated white-cell count, indicating tissue destruction, make the possibility of a myocardial infarct even greater. It would be helpful for diagnostic purposes to have a typical electrocardiogram, but the presence of a

left bundle-branch block is to be taken quite seriously when considered in the light of the total clinical picture. The commonest cause of bundle-branch block is coronary atherosclerosis followed by greater or less degrees of coronary occlusion, whereas other causes, such as rheumatic myocarditis, syphilitic infection and diphtheria, do not seem to have been involved in this case.

The recrudescence of symptoms on the third hospital day may well have been an extension of the myocardial infarction, and it is also quite possible that thrombosis of some of the smaller mesenteric vessels developed, perhaps as a result of emboli from a mural thrombus. This latter complication may cause sudden abdominal pain, vomiting, sometimes diarrhea and shock. Distention usually follows. Occult blood in the stools is common, and according to Wangenstein\* about 5 per cent of such patients appear to have an abdominal tumor. If he did have mesenteric thrombosis in addition to further myocardial involvement, it was of relatively mild character each time he had a fresh attack. The house staff must have been wondering whether or not he had an acute pancreatitis, because of the serum amylase determination, or possibly they were concerned about disease of the gall bladder. Many patients with coronary-artery disease are operated on because they are thought to have an acute surgical abdominal condition, but it is just as bad, if not worse, to overlook a surgical abdomen on the assumption that the discomfort is due entirely to the heart condition.

A dissecting aneurysm must be considered, but this condition usually produces more severe back pain, together with radiation up or down, but particularly to the legs. The sudden development of a right hemiplegia with aphasia may have been due to embolism from a mural thrombus, but it is also consistent with the rupture of an arteriosclerotic vessel supplying the left internal capsule, probably one of the middle cerebral vessels. This was, of course, the immediate cause of death. The cerebrospinal-fluid findings are usually somewhat more abnormal than those in this case but not necessarily so. Whether hemorrhage or thrombosis occurred is uncertain, and either is possible here.

It would be possible to make two or more diagnoses to explain this man's illness and death, but I should prefer to make use of the principle often emphasized by Dr Cabot that one diagnosis should be made that will cover all the major symptoms. The entire picture should be explainable on the basis of hypertensive and arteriosclerotic heart disease, myocardial infarction in the left ventricle, the formation of a mural thrombus, with emboli to the mesenteric vessels and to one of the branches of the left middle cerebral artery (the so-called lenticulostratary group).

\*Wangenstein, O. H. Vascular obstruction. In Christopher F. A. Textbook of Surgery. Fourth edition. 1948 pp. Philadelphia: W. B. Saunders Co., 1945. P. 1057.

DR RICHARD J CLARK I should like to ask Dr Farnsworth how he feels about fluid in the left pleural cavity, in the absence of fluid in the right. Where does he think it comes from? Could it be caused by pulmonary infarction in the left lung, since most patients with congestive failure and hydrothorax have fluid on the right unless there is obliteration in the right cavity?

DR FARNSWORTH I think that an infarct is perfectly possible there

A PHYSICIAN Where would it be coming from? Would you not have to consider a thrombus on the right side?

DR FARNSWORTH With the history as incomplete as it is, I do not believe that I can absolutely state that this man did not have other peripheral circulatory difficulties before admission. I really cannot answer that question

A PHYSICIAN Then you have to make two diagnoses

DR FARNSWORTH Yes, if a pulmonary infarct is assumed

DR ARLIE V BOCK The case as outlined makes Dr Farnsworth's diagnosis quite easy, I think, but our problem while the patient was on the ward was somewhat more difficult. We felt that there was no doubt about the coronary occlusion and myocardial infarction, because of the history of pain and the presence of a certain amount of pulmonary edema. The troublesome feature was the persistence of pain in the left lower quadrant, the obvious distention of the descending and transverse colon suggesting partial obstruction in the region of the sigmoid. Too much attention was paid on our part to the suggestion of diverticulitis, of which there was no clinical evidence. The left lower quadrant was flabby and soft, with no mass or tenderness on pressure. Yet, practically throughout the hospital stay, distention of the colon was present. We could not believe that this was due to diverticulitis. We did not think at that time of the possibility of mesenteric thrombosis. The subsequent attacks of pain made us think of emboli, before the cerebral hemorrhage had occurred. Acute gall-bladder disease did not seem to be likely. The patient had exquisite tenderness, which appeared suddenly and again twenty-four hours later — the sort of thing that one associates with an embolus in the kidney, for example. I should be interested to know whether the pathologist found an adequate cause for the hemorrhage from the bowel, such as a mesenteric thrombosis

DR PAUL D WHITE Serial electrocardiograms might have been helpful. Only one is recorded

DR ISAAC TAYLOR Three were taken

DR TRACY B MALLORY Without significant change, I presume

DR TAYLOR Yes

A PHYSICIAN: Could the leukocytosis and fever fourteen days later have been due to myocardial infarcts?

DR WHITE Probably not. One would suspect some other condition or complication as a rule. I do not remember any case with leukocytosis and fever lasting fourteen days from infarct of the heart alone

DR BOCK. It is interesting that in this case, having suspected renal emboli, as I remember it, we did not find blood in the urine

#### CLINICAL DIAGNOSES

Cerebrovascular accident, probably occlusion of right and left anterior cerebral artery, (?) embolus from left ventricle  
Diverticulitis of sigmoid  
Cholecystitis

#### DR FARNSWORTH'S DIAGNOSES

Hypertensive and arteriosclerotic heart disease  
Myocardial infarct, left ventricle  
Emboli to mesenteric vessels, and to left middle cerebral artery

#### ANATOMICAL DIAGNOSES

*Coronary arteriosclerosis, with occlusion, left anterior descending*  
Myocardial infarction, old and new.  
Mural thrombus, left ventricle.  
Embolism, multiple, left internal carotid artery, splenic and renal vessels  
Infarcts, multiple, to brain, spleen and kidneys  
Chronic passive congestion.

#### PATHOLOGICAL DISCUSSION

DR MALLORY Autopsy showed as the primary disease an occlusion of the descending branch of the left coronary artery, with a large area of infarction in the left ventricle. This infarction had occurred in at least two stages, possibly more. One was a very old fibrous scar, which was undoubtedly months old, then there were some fresh necrosis and some areas that seemed to be in between. On anatomic grounds I am not able to guess how many episodes of occlusion occurred. Overlying the area of infarction was a mural thrombus of the left ventricle, and from that a considerable shower of emboli developed. There were two infarcts of the spleen and multiple infarcts in both the right and the left kidneys. We found nothing else that would explain the abdominal symptoms. The mesenteric vessels were all patent, and there was no diverticulitis. In fact the diverticula were so small that we could not be certain of them at the time of autopsy. The terminal embolus was to the left internal carotid artery and produced extensive softening of the brain, predominantly of the left frontal lobe

DR WHITE What about the left lung base?

DR MALLORY There was 50 cc of fluid in each cavity, with no difference on either side, and no pulmonary emboli.

DR WHITE Was there any evidence of aortitis from the syphilis twenty years previously?

DR MALLORY None.

## CASE 34052

### PRESENTATION OF CASE

A seventy-three-year-old retired man was admitted to the hospital because of nausea and vomiting.

Three days before entry he developed nausea and vomiting of bile-stained food and liquid. On the following day he began to have pain and distention in the lower abdomen. These symptoms progressed. The vomitus became black. He was constipated, but an enema a few hours before admission relieved him of solid brown feces.

The past history was indefinite. The patient had been subject to asthma, hay fever and urticaria. He had four or five episodes of nausea and vomiting without distention in the past year, each lasting three or four days and subsiding spontaneously. There was a tendency to constipation, requiring laxatives for relief. A gastrointestinal series three months before entry demonstrated a duodenal diverticulum. There was no history of food intolerance, colic or acholic stools.

Physical examination revealed a well developed, well nourished man with dry skin and mucous membranes. The abdomen was markedly distended and diffusely tender, especially in the right lower quadrant. No peristalsis was heard. There were bilateral well healed scars from an operation for inguinal hernia. A rectal examination revealed an enlarged prostate. There were anal tags, and there was bloody fluid, similar to the gastric contents, about the anus. The liver was elevated above the rib margin. The diaphragm was elevated and moved well. Examination of the chest was negative.

The temperature was 102.6°F., the pulse 120, and the respirations 30. The blood pressure was 115 systolic, 80 diastolic.

The white-cell count was 6450, with 85 per cent neutrophils, including many immature forms. The hemoglobin was 18 gm., and the hematocrit was 50 per cent. There was 1700 cc of thick, fecal smelling grossly bloody gastric fluid aspirated, which gave a + guaiac reaction. The urine had a reaction of pH 5.5, with a specific gravity of 1.020, gave a + test for albumin and contained no acetone, only occasional red and white corpuscles were found in the sediment.

An electrocardiogram was normal. A plain film of the abdomen showed a massively dilated small bowel.

The patient's condition rapidly grew worse within one or two hours after admission to the Emergency Ward. Thirty minutes after entry he was in mild shock, with a blood pressure of 70 to 80 systolic, 40 diastolic, and a fast thready pulse. He was treated with penicillin, streptomycin, whole blood, "K" solution and dextrose in physiologic saline solution intravenously. A Miller-Abbott tube was passed. On the next day he was weaker and irrational. He passed into coma and died quietly.

### DIFFERENTIAL DIAGNOSIS

DR W. PHILIP GIDDINGS This is the story of a seventy-three-year-old man of allergic constitution, who except for four or five episodes of nausea and vomiting in the previous year, had apparently been in reasonably good health. He was admitted to the hospital after three days of nausea and vomiting with associated lower abdominal pain and distention. He was dehydrated and severely ill, and passed into clinical shock within thirty minutes of his arrival. Therapy did not avail, and he expired within twenty-four hours.

The physical findings were those of dehydration, complete ileus and gastrointestinal bleeding. There were fever and tachycardia of significant degree, and although these might be attributed solely to dehydration or to the effects of an ileus, I believe that in consideration of the silent abdomen and diffuse tenderness we must conclude that the patient had peritonitis.

The laboratory information disclosed that the heart and kidneys were probably normal. There was fairly marked hemoconcentration, as would be expected, and apparently no anemia. The white-cell response was struggling in the right direction, but apparently the toxemia prevented the elaboration of the large numbers of white cells that we should like to see. There was grossly bloody fluid in the stomach and rectum—the description of a + guaiac reaction in the presence of gross blood I take to have been an accidental discrepancy.

DR FRANCIS T. GEPHART The blood was grossly red but it showed a + guaiac reaction.

DR GIDDINGS The two findings are difficult to reconcile.

In the past history we learn of allergies, which I shall dismiss from further consideration. The tendency to constipation may or may not have had any bearing on the problem, there was nothing specific about it, and it could certainly have been incidental. I assume that a gastrointestinal series was done because of the recurrent nausea and vomiting, the finding of a duodenal diverticulum was probably incidental and, I should think, had nothing to do with the present illness.

The following points may give us some clues. Nausea and vomiting were the first symptoms. I infer that this episode somewhat resembled the previous attacks, and that the patient no doubt ex-

to the appeal represents a contribution on the part of every American to the welfare of distressed victims of war, especially children. In many communities the campaign is being co-ordinated with the annual drive of the local Community Chest. Co-operating agencies include United Service to China, American Relief for Czechoslovakia, American Aid to France, Greek War Relief, American Relief for Italy, United Lithuanian Relief Fund, Philippine War Relief of the United States, American Relief for Poland, Church World Service, American Friends Service Committee, War Relief Services and National Catholic Welfare Conference.

American Overseas Aid was organized at the suggestion of President Truman and in answer to increasing demands from community leaders for unification of aid to victims of war. An ancillary purpose is support of American foreign policy—a concrete demonstration of what America is willing to offer, as opposed to propaganda that would exploit the very wretchedness of the people concerned. Substantial relief will do much to reaffirm the value of the United Nations to those who may suspect that the benefits of alliance ceased with the end of military necessity.

But the appeal represents far more than an effort for ultimate political advantage. Americans, who responded willingly to the demands of wartime necessity, can be depended on to extend the hand of humanity to the less fortunate inhabitants of the earth who bore the brunt of the horrors and deprivation of war, the desperate needs of children in particular cannot fail to inspire a generous contribution. Doctors, who work ceaselessly for the amelioration of suffering, will not ignore the call to help relieve those who suffer most. The major reward is in the fine, unselfish giving itself.

#### MASSACHUSETTS MEMORIAL HOSPITALS

THE appointment has been announced of Dr. Philip D. Bonnet as superintendent of the Massachusetts Memorial Hospitals, to succeed Dr. Leverett S. Woodworth who has resigned to accept a position with the Veterans Administration.

Dr. Bonnet, who will assume his new duties on March 1, 1948, was born in Worcester and attended Wesleyan University, from which he graduated in

1932 and Harvard Medical School, graduating with the class of 1936. He has been associated with the Lankenau Hospital in Philadelphia as medical director, and since 1940 as director.

#### MASSACHUSETTS MEDICAL SOCIETY

##### NEW DIRECTORY AVAILABLE

The recently compiled directory of the officers and fellows of the Massachusetts Medical Society is now available at 8 Fenway, Boston 15, and will be forwarded to fellows of the Society on request.

##### DEATHS

**NORTHBRIDGE** — Robert J. Northridge, M.D., of West Upton, died on September 27. He was in his sixty-second year. Dr. Northridge received his degree from College of Physicians and Surgeons, Boston, in 1912. He was a former member of the Massachusetts Medical Society.

**VERDE** — Luigi P. Verde, M.D., of Dorchester, died recently. He was in his seventy-third year. Dr. Verde received his degree from Regia Università di Napoli Facoltà di Medicina e Chirurgia in 1900. He was a pioneer in administering the Schick test for diphtheria and was a former member of the Boston Health Department. His widow and three sons survive.

#### NEW HAMPSHIRE MEDICAL SOCIETY

##### DEATHS

**ALEXANDER** — Anson C. Alexander, M.D., of Penacook, died on January 3. He was in his ninety-third year. Dr. Alexander received his degree from Hahnemann Medical College and Hospital of Philadelphia in 1881. He was a member of the New England Gynecological Society. A daughter, a son, four grandchildren and three great-grandchildren survive.

**ROBINSON** — Richard W. Robinson, M.D., of Laconia, died on November 17. He was in his fifty-fifth year. Dr. Robinson received his degree from Yale University School of Medicine in 1920. He was a former president of the New Hampshire Medical Society and the New Hampshire Surgical Club and was a fellow of the American Medical Association and a member of the New England Section of the American Urological Association. His widow, three daughters, four sons and seven grandchildren survive.

#### A HUNDRED YEARS AGO

One of the remarkable books of the age, which deserves far more attention than it appears to receive, is from the pen of an English gentleman, Thomas Doubleday, Esq., on the true laws of population. He believes that a generous diet, maintained in a family, tends to its ultimate extinction; on the other hand, in new settlements, where a constant effort is demanded to procure the necessities of life, families without children are anomalies. Great prosperity, says Mr. Doubleday, and luxury in living, check increase, starvation, destitution, or a state bordering upon either, stimulate and encourage it. Excessively enriching the soil forces plants to run to straw, excessive eating, gluttony, and drunkenness, prevent reproduction of our species. China and Ireland are outstocked, simply

because there is never food enough, yet the former buoy up their hope with the comforting proverb, that *there never was a mouth without something to put into it* — The Worcester District Society has recently been favored with a legacy of six thousand dollars as a permanent fund, the income of which is appropriated to the purchase of books, apparatus, etc., and which, if it is judiciously managed, will produce, in another half century, a library of much importance to the Society — Dr Henry I Bowditch writes that the *Journal* was the first to announce the discovery of ether and has already recognized an improvement *Chloroform* is to all intents and purposes, *true chloric ether*. It is heavier than water, the taste is pleasant, it excites less cough, its odor does not infect the house of the individual, and a small quantity, averaging 100 drops, suffices to produce insensibility — Dr William R Lawrence reports that the Children's Infirmary in Boston has now been in operation for ten months 174 patients have been admitted, 57 above the age of 15 11 patients died, 2 from typhoid, 2 from ship fever, 1 with pneumonia, 1 with pleurisy, 1 with phthisis, 1 with dysentery, 2 from prostration, 1 from gangrene of the vulvae As to the treatment adopted, very little medicine has been administered, more has been due to the excellent care bestowed upon the children by the matron and the chief nurse, than to any prescriptions of the physician Among the out-door patients there have been a good number of cases of common tinea capitis The dietetic rules of the house have been somewhat rigid, and have been strictly enforced The usual beverage of the patients, until convalescent, has been iced water, and few have asked for anything else The bi-tartrate of potash has been given in a very few instances, when acid drinks were asked for The whole array of pleasant compound beverages has been discarded, and however difficult such a course might be in private practice, it has seemed here to have been attended with increased benefit to the patient — Two notices in commendation of Dr Meigs's Work on Females and their Diseases have appeared in this Journal We relished the style — a flowing, conversational freedom of thought and expression characterizing the whole, and giving even pretty grave parts an inviting aspect The fact could not be denied, as we thought, that the volume was well calculated to have an extensive circulation for Dr Meigs has discovered a lively, agreeable method of gaining the entire attention of the reader Dr Meigs may feel assured of continued popularity — The last arrival from Europe brings the melancholy intelligence of the death of the celebrated surgeon, Mr Robert Liston, at the age of 52 years — Shortly after the commencement of the lecture season now in progress, the Faculty of the Geneva College received an application, by letter, for the admission of a lady to the privileges of the Institution The Faculty

resolved to submit the letter to the class and the class adopted unanimously, resolutions expressing their willingness that the applicant should be received, pledging themselves to treat her with respectful consideration She was accordingly admitted, and has thus far attended the lectures in all the departments, as well as the surgical operations and dissections In so far as her presence in the lecture room has had any influence, it has been conducive to a more strict observance of decorum than is usual with medical classes It is understood that previously to her application to the Geneva College, she had applied to be received at the institutions of Philadelphia, New York City and Boston, but without success Geneva College will therefore be entitled to the distinction, meritorious or otherwise, of first practically exemplifying the experiment of opening the door of medical instruction to a female candidate for the medical profession Extracted from the *Boston Medical and Surgical Journal*, January 1848

### MEDICAL CONFERENCE PROGRAM

Wednesday, February 4—Observations on Amylase in Inhibitors Dr Joseph Volker  
Friday, February 6—The Use of Parasympatholytic Drugs in the Treatment of Bronchial Asthma Dr John Curry  
Wednesday, February 11—The Neurogenic Bladder Dr. Wyland Leadbetter  
Friday, February 13—Recent Advances in Our Knowledge of Blood Coagulation Dr Benjamin Alexander  
Wednesday, February 18—Pediatric Clinicopathological Conference Drs James M Baty and H E MacMahon  
Friday, February 20—Physiological and Pharmacological Factors on Gastric Secretion Dr Byron B Clark  
Wednesday, February 25—The Clinical Aspects of Surgery of the Extrahepatic Biliary Tract. Dr Norman J Wilson  
Friday, February 27—Clinicopathological Conference Drs Chester S Keefer and H E MacMahon

On Tuesday and Thursday mornings from 9 00 to 10 00, Dr S J Thannhauser will give medical clinics on hospital cases. On the second and fourth Friday afternoons of each month therapeutic conferences will be held from 2 00 to 4 00 with round-table discussion, Dr R P McCombs, moderator, Dr Merrill Sosman will conduct x-ray conferences from 4 00 to 6 00. On Saturday mornings from 9 00 to 10 00 clinics will be given by Dr William Dameshek. Medical rounds are conducted each weekday except Saturday by members of the staff from 12 00 to 1 00.

All exercises are open to the medical profession

## HARVARD MEDICAL SOCIETY

A meeting of the Harvard Medical Society will be held in the auditorium of the Beth Israel Hospital on Tuesday, February 10, at 8 15 p m

### PROGRAM

The Effect of a Vitamin A and Carotene Deficient Diet on Psoriasis Vulgaris Richard Hoffmann, M D  
Histochemical Identification of Cellular Enzymes Arnold Seligman, M D  
Recent Studies on Peritoneal Irrigation for Acute Renal Failure Howard Frank, M D  
Studies on the Clotting Defect in Hemophilia Benjamin Alexander, M D, and Andre De Vries, M D  
Studies on Blood Carbonic Anhydrase in Man Mark D Altschule, M D

Subsequent meetings will be held on March 9, April 13 and May 11

## NEW ENGLAND SOCIETY OF ANESTHESIOLOGISTS

A meeting of the New England Society of Anesthesiologists will be held in the Bigelow Amphitheater of the White Building, Massachusetts General Hospital, on Tuesday, February 10, at 8 00 p m. Dr Henry K Beecher's group will present a "Study of Sedatives"

### PROGRAM

An Appraisal of Amidone and Its Isomers as Analgesics Dr Jane E Denton  
The Influence of a Hypnotic (Barbiturate) on Psychomotor Performance. Dr Marcel Verzeano  
Problems of the Measurement of Sleep Dr Oliver H Straus

Physicians and medical students are invited to attend

## NEW ENGLAND DERMATOLOGICAL SOCIETY

A regular meeting of the New England Dermatological Society will be held at the Massachusetts General Hospital on Wednesday, February 11. This meeting is open only to members and invited guests

## TUFTS ALPHA OMEGA ALPHA

The Tufts chapter of the Alpha Omega Alpha will meet at the Boston Medical Library on Wednesday, February 25, at 8:00 p m. Dr Raymond Adams will speak on the subject "Vascular Diseases of the Nervous System"

## NEW ENGLAND PEDIATRIC SOCIETY

The annual meeting of the New England Pediatric Society will be held on Wednesday, February 25  
A detailed program will be announced at a later date

## AMERICAN BOARD OF OPHTHALMOLOGY

The American Board of Ophthalmology will hold practical examinations in Baltimore from May 20 to 25 and in Chicago from October 6 to 9. Written qualifying tests will be held annually, probably in January of each year. Applications for the January, 1949, written qualifying test must be filed with the Secretary before July 1, 1948.

## MISSISSIPPI VALLEY MEDICAL EDITORS' ASSOCIATION

Dr Morris Fishbein, editor of the *Journal of the American Medical Association*, will give an instructional course in medical writing at the annual meeting of the Mississippi Valley Medical Editors' Association, to be held in Springfield, Illinois, on September 29 during the annual meeting (September 29-October 1) of the Mississippi Valley Medical Society in that city. No registration fee will be charged to members of the Association.

## MEDULLOBLASTOMA CEREBELLI\*

Diagnosis, Treatment and Survivals, with a Report of Fifty-Six Cases

FRANC D. INGRAHAM, M.D.,† ORVILLE T. BAILEY, M.D.,‡ AND WILEY F. BARKER, M.D.§

BOSTON

SINCE the first description of medulloblastoma cerebelli was published by Bailey and Cushing<sup>1</sup> in 1925, this rapidly growing tumor of the cerebellum has been recognized as occurring most often in children and leading to the abrupt onset of increased intracranial pressure and cerebellar dysfunction. Evidence has accumulated, however, that this typical syndrome is not always found in patients with medulloblastoma cerebelli and also that certain other tumors of the cerebellum give clinical symptoms indistinguishable from those of medulloblastoma. It is well known that medulloblastomas are much more successfully treated by irradiation than by radical extirpation. The place of surgery in the treatment of medulloblastomas, the amount of x-ray therapy desirable and the results to be expected are still open questions. We are therefore recording our experiences with medulloblastoma cerebelli with particular reference to the results obtained with various forms of treatment.

The series is composed of 56 patients from the following sources: patients seen at the Peter Bent Brigham Hospital since 1930, some of whom had originally been treated before that date in Dr. Cushing's clinic, and all the patients in the records of The Children's Hospital, many of whom were transferred to the Peter Bent Brigham Hospital for treatment before 1930. For this reason, some of these cases have already been reported elsewhere by other authors.<sup>1-12</sup> We have excluded from the series examples of the so-called "cerebral medulloblastoma," since it is not certain that they are identical pathologically with cerebellar medulloblastoma and since the clinical behavior of these two types of tumor is entirely different. Although medulloblastoma cerebelli is largely a tumor of

childhood, evidence that it occurs in adults more often than was previously thought is accumulating.<sup>12-14</sup> In all cases the diagnosis of medulloblastoma cerebelli in this series has been based on histologic identification, and sections of each tumor have been reviewed to exclude any not conforming to the present concept of this lesion. The specific anatomic locations are shown in Table 1. It is interesting to note that 15 of the 56 tumors did not occupy the classic midline position in or above the fourth ventricle.

Some authors<sup>6</sup> have believed that a difference exists between tumors arising in the midline, in the lateral cerebellar hemispheres and in the cerebello-pontine angle or in the pons itself. In our series there were no apparent differences in the natural history of the tumors in these sites. The only objective finding that varies in these locations is the average age of the patients, the ages were higher with pontile tumors than in those of the cerebellum (Table 1). However, the numbers involved are so small that the statistical significance of the difference in age is doubtful.

The distribution of all patients in the series according to age is in agreement with other reports. Twenty-four were in the second five years of life, and forty-two were in the first decade, but typical tumors were also seen in patients as old as thirty-seven and sixty-five years.

Distribution by sex was about equal, there were 31 males and 25 females.

Symptoms had been present on the average for slightly more than three months before the patient was brought to the hospital. The patient seen earliest after the onset of symptoms had noticed difficulty for only a week, and the longest pre-hospitalization period was twenty-four months. This is in agreement with the experience of many other clinics that the onset of symptoms in medulloblastoma is usually, but not always, rapid and that the symptoms follow a pattern of disturbed cerebellar function and increased intracranial pressure. It should be pointed out that medulloblastoma is

\*From the Neurological Institute, Children's Medical Center, the Surgical Service, Peter Bent Brigham Hospital, and the Departments of Surgery and Pathology, Harvard Medical School.

†Assistant professor of surgery, Harvard Medical School; neurosurgeon in-chief, Children's Hospital; chairman, Neurological Institute, Children's Medical Center.

‡Assistant professor of pathology, Harvard Medical School; neuropathologist, Children's Hospital; vice-chairman, Neurological Institute, Children's Medical Center.

§Formerly assistant resident in surgery, Peter Bent Brigham Hospital and Children's Hospital.

not the only tumor in the posterior fossa that causes abrupt onset of symptoms. Tumors that are much lower in malignancy and far more satisfactorily treated surgically sometimes give rise to clinical pictures indistinguishable from those due to medulloblastoma. For this reason, we believe it to be of the utmost importance to make a biopsy in each patient before roentgenotherapy is begun.<sup>11</sup>

Sixty explorations of the posterior fossa were carried out on 53 patients in this series. In 3 cases surgery was regarded as inadvisable in view of the condition of the patient. Biopsies were made in

the course of these explorations. When larger portions of the tumor were accessible and could be extirpated without additional risk to the patient, this was done. In 3 patients it was necessary to expose medulloblastomas of the cerebellopontine angle through an occipital craniotomy after the suboccipital approach had failed to give adequate exposure. In 6 patients burr holes were made as procedures separate from a surgical approach to the tumor.

When the circulation of the cerebrospinal fluid was not re-established with certainty by removal of tumor or by freeing of adhesions, some further

procedure was necessary to protect it. A tube was inserted for this purpose by the method of Torkildsen<sup>15</sup> in the course of seven of the sixty posterior-fossa explorations. The tube used in recent operations was made of polyethylene,<sup>16, 17</sup> which causes less tissue reaction than the rubber catheters formerly employed for the purpose. In 3 other patients third ventriculostomies were carried out as separate procedures, a right frontal approach being used. We prefer to use third ventriculostomies for older patients, but they have not been so successful in younger ones because the opening often closes

after a time. It is our impression that these operations have given the patients a maximum period of freedom from symptoms followed by a rapid downhill course in the terminal phases.

In all, seventy-two operations were performed on 53 patients, with an operative mortality of 32 per cent.\*

It has long been recognized that the medulloblastoma is more prone than any other glioma to

TABLE 3 *Clinical Symptoms Related to Metastases*

SYMPTOM	NO. OF PATIENTS
Somatic pain	7
Cord bladder	5
Complete paraplegia	2
Horner's syndrome	1

extend to the meninges and to produce secondary deposits within the cerebrospinal axis. The occurrence of metastases was demonstrated in 19 cases (Table 2). Of these, 10 showed distant spinal or cerebral seedings, the remaining 9 were local subarachnoid extensions. It is possible that the operative procedure is at times responsible for the dissemination of tumor particles. That this is not the only means of subarachnoid spread is shown by 2 cases in which metastatic implants were seen at the time of the first operation.

Not all these metastases caused definite symptoms, in 2 cases, however, a definite paraplegia was present. Cord bladder occurred in 5 cases, and 7 patients complained of severe pain in the distribution of spinal segments, which could be explained by no other cause (Table 3). One patient was even subjected to a laparotomy because of persistent right-lower-quadrant pain. This same

child's death was ultimately due in large measure to transection of the spinal cord by tumor.

Another complication was acute gastric ulceration, which occurred in 3 patients (Table 2). In only 1 of these cases were the perforation and extent of the resulting hemorrhage and peritonitis sufficient

\*Following Cushing's precepts,<sup>8</sup> we regarded any patient who died in the hospital during an admission in which an operation was performed as an operative death, although in some cases the cause of death was unassociated with the immediate operative procedure.

to be regarded as the cause of death. All 3 cases of postoperative intracranial hemorrhage were fatal. The only 2 cases of bronchopneumonia that were diagnosed at autopsy were terminal, but not agonal, and cannot be considered the sole cause of death. Of the 2 cases of wound infections, 1 was a fulminating streptococcal meningitis, which was fatal on the third postoperative day. The other was a slight infection of the superficial layers of the wound, which proceeded to heal well after only a brief delay.

Experience has shown that x-ray therapy is by far the most effective treatment for medulloblastoma cerebelli. Three patients in the series died before the institution of definitive treatment. Fourteen more patients were operated upon but did not receive roentgenotherapy in the early part of the series before modern therapeutic radiation was available. The majority (39 patients) were operated on and received therapeutic irradiation in addition. There were 9 patients still living on January 1, 1946—a case mortality of 84 per cent.

The survival of all patients is shown in Table 4, together with the amounts of roentgenotherapy received, and with an estimated "symptom-free" period of survival. These periods of survival are calculated from the date of the first hospital admission. The termination of the "symptom-free" period is based on purely subjective estimates from correspondence and outpatient records and has no objective criteria. It is the prolongation of this period, however, that is the chief goal toward which our therapeutic measures have been directed.

Six of the patients treated received undetermined amounts of roentgenotherapy, in 10 other cases completely accurate figures are not available, but figures representing minimum known dosages are used. In the remaining 23 patients, the dosages are known to be accurate.

Only 1 patient who received less than 4000 r of total therapy survived more than fourteen months, the average survival being slightly under eight months (Table 4).<sup>\*</sup> One of these patients was still living fourteen months after admission, but was in a nursing home for terminal care.

Fifteen patients received between 4000 and 10,000 r, with an average survival time of thirty-one and a half months. If the patient who survived for twenty-two years<sup>12</sup> is excluded, the average survival time falls to fourteen months. The average survival of all the patients who have died is seventeen months, the average "symptom-free" period of these same patients is slightly more than eleven months, excluding the patient who survived twenty-two years, this is lowered to nine months.

None of the patients who received more than 10,000 r is still alive, but the average survival period is fifty-four months, the least being seventeen

months and the greatest being slightly over twelve years. The "symptom-free" survival in this group is over forty-four months. It must be recognized, however, that although the larger dosages of irradiation may be assumed to be the cause of a longer survival, it is also true that only in those patients who lived for a fairly long time after admission could such large dosages be accumulated.

Several of these patients received unusually large total dosages over the course of several years, the biggest being approximately 30,000 r to the skull and spine over three and a half years. Some authors<sup>18</sup> have doubted the advisability of using such large dosages of therapeutic irradiation and have published reports of degenerative changes when dosages between 10,000 and 15,000 r had been used. In no cases in this series were any similar degenerative changes ascribable to roentgenotherapy specifically noted.

Systematic records of responses to x-ray therapy are not available on several of the patients with

Undetermined	11

<sup>\*</sup>The number of living patients is 9.

<sup>†</sup>One patient also had an upper intestinal ulceration.

spinal metastases, 4 cases with adequate records demonstrated at least some response to therapy—in 1 case almost complete remission of pain for four years.

The clinical difficulties due to the irradiation were leukopenia, vomiting and acute cerebral edema. In 6 cases treatment was interrupted because of leukopenia (this occurred twice in 1 patient). Vomiting followed the irradiation in most patients, but in only 1 case was it of such magnitude as to require cessation of treatment. One patient died of cerebral edema after one treatment of 150 r. Autopsy showed a very edematous brain, with a marked pressure cone. The child also had an acute gastric ulcer, but this was not regarded as an important factor in the fatal outcome, since there was no evidence of perforation or bleeding from the ulcer at autopsy.

Tabulation in terms of survival periods without consideration of form of therapy reveals that there are 7 cases of three years' survival (12.5 per cent). Of these, only 3 went on to the five-year mark (5.4 per cent), 2 patients survived more than ten years (3.6 per cent). One of the last is still living

<sup>\*</sup>In calculations of these survivals only the patients who lived to receive any roentgenotherapy are included.

and in fairly good health twenty-two years after her original admission<sup>12</sup>.

Table 5 shows the causes of death in the entire series. Placed together are 20 fatal cases that can be ascribed almost entirely to one factor — increased intracranial pressure. Nine other deaths may be attributed to a combination of increased pressure, local edema, local trauma, local extension of the tumor and peripheral shock. In 11 cases no definite cause of death could be assigned, the patients having died outside the hospital.

Since the patients reported in this series have been treated by more than one neurosurgeon and over a long period, the forms of therapy used have varied considerably. On the basis of this experience our present choice of treatment has been exploration as soon as the diagnosis of a posterior-fossa tumor is made. Temporization with preliminary trials of roentgenotherapy does nothing but jeopardize the vision of children who have a benign cerebellar tumor<sup>11</sup>. If, at operation, it is possible to remove more than enough tissue for a biopsy, a larger portion of the tumor is resected, and a means for circulation of the cerebrospinal fluid is provided. As soon as the wound is healed, the patient is given an intensive course of roentgenotherapy, not only to the cerebellar area but also to the spine, in an attempt to destroy any metastatic seeding that may already be present. This first course of irradiation usually amounts to a total of 5000 r. It is followed in six months — sooner if the symptoms warrant it — by more irradiation through cerebellar portals. If there is evidence of spinal involvement, appropriate roentgenotherapy to the spinal portals is instituted. Re-exploration is indicated in the presence of obstruction to the circulation of cerebrospinal fluid, and an attempt to short-circuit the flow, by a tube as suggested by Torkildsen<sup>15</sup> in younger patients or by a third ventriculostomy in older patients.

#### SUMMARY

Fifty-six cases of medulloblastoma cerebelli are described, and the results obtained by various forms

of therapy evaluated. It is of great importance to establish histologic proof of the presence of medulloblastoma before roentgenotherapy is begun. Short-circuiting operations for the relief of increased intracranial pressure have been of considerable assistance in selected cases. Vigorous treatment of cerebellar medulloblastomas with irradiation is always indicated. Even if permanent cure can rarely be accomplished, it is possible to prolong a relatively "symptom-free" period of survival, which may then be followed by a brief downhill course.

## THE PRACTICAL IMPORTANCE OF MODERN CONCEPTS OF PSYCHOSOMATIC RELATIONS\*

ALFRED O. LUDWIG, M.D.†

BOSTON

THE term psychosomatic in its present-day usage serves commonly to designate a group of diseases with organic changes in which emotion is thought to play an important etiologic role. It is unfortunate, however, that there is a tendency to think of this approach as constituting still another specialty within the body of medicine. It would be far healthier if a broader concept could be adopted in which the attempt to study and describe both the physical and emotional aspects of illness could be viewed as a step toward the unification of all medical knowledge as it pertains to disease in a patient.

The recent investigations in this field are an approach toward incorporating into the structure of medical science what used to be known as the art of medicine. Everyone is familiar with the consummate skill of the experienced general practitioner, which combined a detailed personal knowledge of the patient, his past life and his family, with sound medical understanding as well as a great intuitive grasp of emotional problems and a warm friendly support. Striking therapeutic success and an excellent doctor-patient relation were often the result. However, these efforts could never be more than intuitive or empirical, nor could they be made predictable or manageable until they were subjected to careful psychiatric investigation.

To consider the patient as a person one must first accept the reality of emotional reactions. For example, one should not forget that nausea and vomiting may be caused entirely by strong emotions as well as by structural changes or by irritating substances in the stomach. Somewhat more difficult to visualize but now well established is the concept that emotion can eventually produce structural changes in the body. Once this is admitted a far broader view of the nature of disease must follow. It is vital that the patient be made to feel that he — and not his body alone — is the focal point of the doctor's interest.

From this it follows that psychogenic illness or any disturbance in which one cannot demonstrate organic change should no longer be considered as imaginary or even perhaps as consciously planned by the patient in an effort to deceive. Such an attitude defeats therapy before it begins. It brands the patient as a liar and denies the existence of his symptoms. One must make certain that the pa-

tient's feelings, his personal relationships, his life situation and his reaction to his environment are all subjected to the same painstaking scrutiny as his physical body and its symptoms. His emotions should be examined with the same objectivity as his organs, and here it is well to caution that moral judgment regarding behavior has no place in medical treatment. Irritating or annoying actions can be as much a part of a pathologic picture as organic disease and should receive from the doctor the same dispassionate appraisal, never unreasoning retaliation.

The first group of disorders of importance to the practicing physician are neuroses that manifest themselves by somatic disturbances, such as gastrointestinal, cardiovascular and skeletal symptoms. It has been estimated that from 30 to 50 per cent of all the patients seen in medical outpatient clinics are of this type.

It is highly important that such patients be handled properly from the outset. This implies that one take a careful medical history, which should include at least an attempt to outline the gross personality traits as they pertain to the illness. An adequate physical examination should follow, with special attention to the part of the body that is the seat of the complaint. Necessary laboratory work should be done when indicated.

At this point the physician can make or break the successful treatment of the case. If no significant organic changes are demonstrated, the patient should be so informed and should then be instructed, in the simplest words, concerning the mechanism of production of psychogenic symptoms. It is well not to use ambiguous or unfamiliar terminology and to be as definite and precise as possible, lest misapprehension arise. For example, many a patient becomes "heart conscious" and develops or perpetuates cardiac symptoms after injudicious remarks, too prolonged attention to examination without explanation or overemphasis upon nonsignificant findings such as murmurs and disturbances in rhythm. It is well always to minimize when possible, especially with these apprehensive patients. An evaluation of the patient's personality will give valuable clues regarding how much and what he can be told in such situations. All explanations should be clear and concise, and the patient should be encouraged to ask questions to allay any fears that he may have. Such care takes little extra time and results in very valuable therapeutic effects.

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1947.

†Assistant psychiatrist, Massachusetts General Hospital; staff psychiatrist, Robert Breck Brigham Hospital; member, Advisory Committee, Neuropsychiatric Service, Veterans Administration.

If the disease is purely psychogenic, treatment should not be organic. Every neurotic person seeks to evade responsibility by falling back upon an organic diagnosis. It is more comfortable and more acceptable to explain symptoms as due to alien infections or other external causes than to accept personal responsibility as one must if one's own emotions, be they conscious or unconscious, are at fault. In this respect the experiences with such disorders during the war gave valuable information. Disability from acute somatic symptoms, which were due largely to emotional causes, was common in infantry soldiers under fire. When such men were asked for their explanation of the origin of their disturbances most were prone to blame external agents, few admitting that fear had played any part in making them ill. In this situation, an organic illness furnished an honorable way out in which fear had no part. A recognition of this chain of events and explanation of the psychologic aspects salvaged many useful soldiers for further action when it was accomplished soon after the onset. However, if the doctor made the error of accepting the patient's explanation of an organic external agent as the sole cause of his illness, he supported his rationalization and provided the neurotic process with the needed justification. All these men felt great guilt at leaving their buddies. The longer they were hospitalized, the greater the guilt and consequent need for further justification. Under such conditions recovery was greatly hampered and indeed often became impossible. Although such extreme pressures do not pertain to civilian patients, the underlying principles are the same, and the same precautions must be taken.

Unnecessary surgical procedures are especially harmful. In the presence of severe neurosis, the patient may often unconsciously seek such treatment in part as punishment for severe guilt feelings. Unless the indications are very clear-cut or an emergency exists, surgical procedures are best avoided in the presence of evidence of hysteria or other severe neurosis. Grave errors have been made in such situations with the newer operations to relieve pain. Such unwarranted interference not only has failed to give relief but also has too frequently led to repeated surgical measures that made eventual psychiatric care much more difficult.

There is no doubt that there is still a large group of patients in whom persistence of disability must be blamed on the injudicious medical management of psychogenic symptoms. Such cases are unnecessary and preventable. Usually, the treatment does not require specialized psychiatric knowledge. Adherence to the simple principles of considering the patient as a person, adequate examination, avoidance of unnecessary diagnostic procedures, simple explanation and reassurance usually suffices to alleviate or remove the symptoms and to restore

self-confidence. In severe cases, of course, specialized psychiatric treatment must be utilized.

Another important category of illness is made up of disorders in which recent studies have shown that emotional influences acting over longer or shorter periods result at first in disturbed physiology and eventually in structural change. Peptic ulcer is the simplest example. In this condition disturbed emotions lead to hypersecretion of gastric hydrochloric acid. When this has persisted long enough under certain conditions actual ulceration supervenes. Ulcerative colitis is another serious disorder in which emotional factors play an important role. In both these diseases dangerous complications and even death are not infrequent. Other disturbances in this group are the allergic illnesses such as asthma, hay fever and urticaria, certain skin diseases, such as eczema and neurodermatitis, migraine, possibly certain cases of epilepsy, hypertension and rheumatoid arthritis.

Addiction to alcohol and to drugs has long been considered a purely psychiatric disorder. Another addiction—namely, that to food,—which leads to simple exogenous obesity and which may result in the complications that are secondary to pathologic accumulations of fat, has been shown to have important psychologic aspects.<sup>1, 2</sup>

There seems to be emerging slowly a clearer understanding of the personality structure of persons who become ill in this way or who react with their bodies to certain emotional crises. These patients, usually unbeknown to themselves or others, appear to have remained or to have been pushed back to extraordinarily primitive and early stages of emotional behavior. They manifest an extreme degree of dependence upon certain key figures around them. This dependence on closer survey turns out to be so exaggerated that it suggests an almost symbiotic relationship. The loss of these key persons by death or by separation produces catastrophic helplessness and is often followed by organic illness. Lindemann<sup>3</sup> has reported that in 33 of 41 cases of ulcerative colitis, the disease began after the loss of important persons in the patient's life. The onset of rheumatoid arthritis after the death or illness of close relatives has frequently been reported in the past<sup>4, 5</sup> and has been observed in a small group of carefully studied patients.<sup>6</sup>

This extreme degree of insecurity and need for the support of others is manifested in various ways. It may be displayed openly as a childish, clinging, extremely demanding and grasping attitude with marked impatience and intolerance to any discomfort. On the other hand it may be completely hidden. In this event only the defense against the underlying weakness is seen in the form of an exaggerated false front of self-reliance and independence. The inadequacy of this defense becomes apparent when it collapses before any event that forces the patient into a dependent attitude. Such an event may be

the loss of economic status, the loss of key figures or separation from the family, a group or even a familiar environment. Loss of body substance or parts of the body, by injury or by operation, may also be a precipitating event. Apparently, many of these persons are extraordinarily dependent on the constant presence of outside help for the maintenance of security and psychologic integrity.

Coupled with this extreme degree of dependence is an exaggerated intensity of emotion. In consequence, these patients become extremely controlled outwardly and are usually considered to be cold and unfeeling. They fear any loss of control because it may result in an explosive and overwhelming outburst. It is as if they could express this intensity only through the channel of bodily symptoms.

Contact is difficult and they tend to live in isolation. Personal relations are difficult except on a superficial level. Their greatest fear is that of complete helplessness. Organic illness brings some recompense in that it is accompanied by the security secondary to attention and medical care. However so great is the fear of relying on others, paradoxically, that the patients may actually resist treatment. It is not infrequent to find this reaction in patients with rheumatoid arthritis, who persist in activity even though they know they should be in bed. Resistance to the effect of drugs—that is to being controlled by them—is another idiosyncrasy that is occasionally observed.

Eating is one primitive method of solving difficulties employed by these patients. For them, eating can assuage a sense of loss, of depression or of deprivation, and on the other hand it may serve to relieve anger or rage. At times it seems as if any discomfort can be relieved by this means. It is interesting that eating disturbances are not infrequent in such patients. Large fluctuations in weight, from obesity to pathologic weight loss, are common in the histories. Oral drug addiction is not rare, and one need recall only the very troublesome craving for tobacco that appears in certain patients with peptic ulcer, as well as the propensity for drug addiction in patients with rheumatoid arthritis even in the absence of a significant degree of pain.

These patients appear to have extremely loosely organized personalities. Their self-confidence is easily shattered by any deprivation or loss, whether of support from the outside or of a part of the body, by injury or operation. They are greatly dependent on outside help and react to insecurity with violent emotions. Responses are primitive and of total intensity. In this primitive stage such strong emotions are expressed by physiologic changes rather than by the more mature methods of physical activity, the outward expression of feeling or by verbalization.

What are the implications for treatment? To influence such patients, it is essential to establish con-

tact with them. This requires a very warm, friendly and giving type of approach, such as is usual and customary for the practitioner of medicine. It has been shown that therapeutic efforts may be defeated by the use of the passive psychiatric technique of exploration, which requires that the patient give a great deal of himself in words and ideas while receiving little in return.<sup>2</sup> Such efforts make demands on these patients of which they are incapable, and they are resisted with silence and hostility. They may result in actual exacerbation of bodily symptoms.

Every known therapeutic device must be utilized to demonstrate the doctor's interest and his willingness to help. This may be aided by attention to every detail of comfort and care from the medical, nursing and psychologic points of view.

It will be clear that such vulnerable persons will be suspicious and distrustful, and therefore it is vital that an attitude of extreme honesty be maintained at all times. If mistakes are made, they must be freely acknowledged. Strong support and reassurance are essential, and it is often necessary to infuse one's own optimism, confidence and strength of will into the patient. This he accepts by identification. The doctor may have to put himself temporarily into the role of the lost key figures or seek to manipulate the environment so that they are replaced.<sup>3</sup>

One must never try to push these patients too hard or too fast. Pressure is felt as rejection and hostility and either is strongly resented or produces exacerbation. One must avoid becoming annoyed by demanding and grasping attitudes. Often, these persons deliberately try one's patience by overt hostility. It is best to inquire into the reasons for such behavior, before retaliating. Many of them suspect that the entire world is hostile and cannot believe that anyone has any good intentions. The best results are obtained by gentle suggestion. One should attempt by every means to produce a therapeutic situation in which doctor and patient cooperate toward rehabilitation.

Restoration of maximal working efficiency should be a therapeutic goal equal to cure or alleviation of the disease itself. Emotional factors that may contribute to the dependency should be explored and removed whenever possible. Social service, by investigating and lightening the burden of family and environmental stresses, has much to offer. Occupational therapy should be so organized that it uses methods commensurate not only with the patient's physical ability but also with his intellectual and vocational aptitude. Under such conditions it can greatly assist rehabilitation. Vocational guidance, with retraining when indicated by the limitations of illness, deserves a larger place in organized medicine. Greater utilization of every facility available in the hospital and elaboration of

the concept of the therapeutic team should add greatly to the speed of rehabilitation

A word regarding the role of compensation and pension in disease is indicated. The justice and humanity of the principle of compensation for injury or illness sustained in industry or war are freely conceded, but a much greater understanding of the insidious and highly crippling effects of a continuing pension must become more widespread among the medical profession. Everyone has seen patients pushed into and maintained in chronic invalidism through the payment of weekly or monthly pensions. Especially if he is already insecure, the patient clings to his pension as his only lifeline, which although it is pitifully inadequate, protects him from complete helplessness. He is afraid to take steps toward independence even when there are no longer adequate physical reasons for disability because of the fundamental loss of self-confidence secondary to his illness. By the same token he cannot give up his only prop of compensation. Such behavior is neither conscious nor deliberate but represents a secondary neurotic dependency that is nurtured by the continued pension. From the point of view of rehabilitation, continuing compensation is not humane but hampers recovery. A review of present attitudes toward these practices is necessary, and lump-sum settlement offers one possibility for a solution.

Recent advances in the treatment of acute infectious disease have greatly decreased the dangers and economic loss from these illnesses. This requires that even greater attention be given to the large group of chronic and disabling diseases. If the patients are to be rehabilitated, the emotional relations that enter into the causation and treatment of their disease must receive much more study

and consideration, and this knowledge must become part of the thought and practice of every doctor.

In certain clinics in this country the psychiatric service has placed representatives in every outpatient clinic, surgical or medical.<sup>7</sup> Such close working together with every specialty has greatly furthered the understanding of the emotional aspects of illness in every special field and has made psychiatric knowledge much more available throughout the hospital. A wider application of such co-operation is to be welcomed.

It is likely that a new approach will have to be found to teach medical students these aspects of disease. Descriptive psychiatric teaching has its place, but it appears essential for every medical student to understand fully the psychologic development and the personality structure of normal as well as abnormal persons. It would be well if such teaching became an integral part of the entire medical curriculum.

Only complete consideration of all aspects of every patient and his illness — physical, emotional or environmental, and no matter in what special area of medicine — can eventually give an adequate understanding of the true mechanisms of disease and the most efficient and rational treatment.

## THE CYTOLOGIC METHOD IN THE DIAGNOSIS OF CANCER\*

MAURICE FREMONT-SMITH, M D,† RUTH M GRAHAM, B S, AND JOE V MEIGS, M D ‡

BOSTON

TO MAKE a balanced judgment is always difficult. It is a human failing to see things either black or white and, often with insufficient evidence, to render an immediate and final decision either for or against. We shall describe a new test for cancer and present evidence of its value. It is not our contention that this new test should compete with biopsy or replace that method in the diagnosis of cancer. The electrocardiograph did not supersede the older methods of diagnosis in the detection of diseases of the heart. The eyes, the ears and the hand still remain the tried means of evaluating the cardiac state. Nevertheless, the electrocardiograph not infrequently reveals the presence of myocardial changes incapable of detection by the unaided senses, and it has become an essential aid in the interpretation of many cardiac conditions. The diagnosis of cancer by cytologic examination of body fluids bears a similar relation to diagnosis by the older methods. Not infallible, the new method nevertheless supplements the biopsy and in some cases gives information that the biopsy cannot give. Just as the electrocardiograph is now an indispensable aid in cardiology, so we consider the cytologic examination an essential complement to biopsy in the diagnosis of cancer.

Diagnosis by the cytologic method depends upon the fact that malignant tumors upon any free surface desquamate tumor cells into the surrounding medium. We are familiar with the continuous desquamation of normal cells, as evidenced by the constant presence of squamous cells in the vaginal secretion, the sputum and the urine. There is some evidence that the surface cells from malignant tumors desquamate even more rapidly than normal cells of similar origin.

For many years pleural and ascitic fluids have been examined for malignant cells, their presence depending upon the same property of desquamation. The method was first made applicable to other than metastatic tumors by Papanicolaou, who, in 1928, recognized cancer cells in the vaginal secretion of women with cancer of the uterus and on the basis of this observation published in 1941 the description of a new method of diagnosis of uterine cancer.<sup>1</sup> A detailed technic of the vaginal-smear method has

been described.<sup>2-4</sup> Briefly, a dry pipette with a capillary opening and capped by a rubber suction bulb, is introduced into the posterior vaginal fornix, the bulb is released, and the pipette withdrawn. The aspirated fluid is blown upon a previously marked glass slide, immediately fixed in equal parts of ether and 95 per cent alcohol, stained and examined for cancer cells. Criteria for the recognition of such cells is found in the articles to which reference has been made. Only after long experience may cancer cells be confidently distinguished from the many types of normal cells present in the vaginal secretion.

The value of this diagnostic method has been well established. Papanicolaou's<sup>1</sup> original report has been confirmed.<sup>4-6</sup> In a controlled study Hertig<sup>8</sup> obtained positive smears in 39 of 40 cases of carcinoma of the cervix and in 15 of 18 cases of carcinoma of the fundus. Eight positive and five negative smears were encountered in 13 cases of pre-invasive carcinoma of the cervix.

During the past five years in the Vincent Memorial Laboratory, 3710 cases have been studied by vaginal smear with a total diagnostic error of 2.8 per cent. Of 3327 cases without cancer, a mistaken positive diagnosis was made in 55. This represents an error (negative cases called positive) of 1.6 per cent.<sup>5</sup>

A recent publication suggests that many patients hitherto considered to have early cervical carcinoma, presenting but a short history of bleeding, or a minimal visible lesion may nevertheless be in an advanced stage of the disease, some even with metastases.<sup>10</sup> There is evidence that carcinoma of the cervix presents neither symptoms nor signs for as long as eight years after its inception.<sup>11-13</sup> In 47 cases of preinvasive carcinoma of the cervix reported by Pund and Auerbach<sup>10</sup> only 1 out of 4 patients had abnormal bleeding, and the cancer was not recognizable to inspection in a single case. If the gynecologist cannot visualize any suspicious area, he must take a biopsy specimen (or three or four specimens) hit or miss, 25 per cent of such biopsies fail to include epithelium,<sup>14</sup> and a larger number fail to include the malignant area.

In the diagnosis of very early carcinoma of the cervix, the vaginal smear is not infrequently more accurate than the biopsy.

The following and similar cases demonstrate that preinvasive carcinoma is often more successfully diagnosed by cytologic than by histologic examination.

Of 285 cases of cervical cancer 31 have been missed by smear. In 20 of 98 cases of endometrial carcinoma the smear was negative. It is evident that the vaginal smear is most accurate in cervical and less satisfactory in the diagnosis of fundus carcinoma.

†From the Vincent Memorial Hospital (the Gynecological Service) of the Massachusetts General Hospital and the Departments of Medicine and Gynecology, Harvard Medical School.

‡Associate physician, Massachusetts General Hospital.

§Clinical professor of gynecology, Harvard Medical School, chief of the Vincent Memorial Hospital (Gynecological Service), Massachusetts General Hospital; surgeon, Poudre Hospital; gynecologist, Palmer Memorial Hospital.

A 49-year-old woman, 3 years after the menopause, was given estrogens because of arthralgia. After 3 months of estrogen therapy, bleeding for 1 day occurred. The cervix was normal to inspection. A vaginal smear was positive. Biopsies taken from three areas in the cervix showed chronic cervicitis. A complete hysterectomy was done. The cervix was grossly normal. However, after the cervix had been sectioned, carcinoma was found in an area not over 0.5 mm in diameter.

A 42-year-old woman was admitted to the hospital because of a lump in the right breast, which proved to be benign. Pelvic examination showed a cervical erosion and leukoplakia. Cytologic examination of the vaginal secretion was positive for cancer. The diagnosis on a biopsy specimen was leukoplakia. A total hysterectomy was performed. Histologic examination disclosed preinvasive carcinoma of the cervix.

Seventeen cases of preinvasive carcinoma of the cervix, in which vaginal smears were positive in 15, have recently been reported.<sup>10</sup> Of thirteen biopsies taken from these 17 patients histologic diagnosis on the initial biopsy was positive in only 5. Four patients had had no symptom, a neoplastic lesion was unsuspected and was discovered only by routine vaginal smear.

### CANCER OF THE LUNG

Because pulmonary neoplasms desquamate into the bronchial secretion, the sputum has been studied for possible carcinoma of the lung. Dudgeon<sup>14</sup> was the first to introduce wet fixation as a diagnostic method. Gower,<sup>15</sup> Wandall<sup>16</sup> and others have obtained by this method a diagnostic accuracy of 60 to 80 per cent. Seed and Graham,<sup>17</sup> in our laboratory, have examined a single sputum specimen from each of 250 cases. A correct diagnosis for or against cancer was made in 73 per cent. In cases suspected of cancer the diagnostic error can be reduced by the examination of several specimens of sputum. It is important to note that in this series of 56 cases of primary pulmonary carcinoma, 7 cases were operable, sputums from 6 of these contained cancer cells.

### CANCER OF THE URINARY TRACT

A diagnosis of cancer of the urinary tract may be made by the examination of smears obtained from the urinary sediment. Our diagnostic accuracy has approximated 50 per cent. The following cases illustrate the value of the method.

I M, a 60-year-old patient, complained of hematuria and acute retention. Cancer cells were found in the urinary sediment. Cystoscopy showed cystitis, but no evidence of neoplasm. A biopsy taken at that time revealed only chronic inflammation. A total cystectomy was performed. Histologic examination disclosed cancer of the bladder, Grade II-B.

A S, a 79-year-old patient, had recurrent hematuria. Retrograde pyelograms showed a filling defect in the right kidney consistent with blood clot, but the possibility of tumor could not be excluded. The urinary sediment was positive for cancer. A nephrectomy was performed, cancer of the renal pelvis, Grade II-B, was found by the pathologist.

Until more statistical evidence is available, however, we believe that major operative procedures should not be undertaken on the basis of a positive

cytologic diagnosis of the urinary sediment unconfirmed by other examinations.

### GASTRIC CARCINOMA

The early detection of cancer of the stomach has so far proved an almost insoluble problem to the surgeon. Between 10 and 20 per cent of lesions that later prove malignant continue to be diagnosed as benign. Diagnosis of lesions that are grossly benign but histologically malignant is impossible either by x-ray examination or by gastroscopy, moreover, the surgeon at the operating table is frequently unable to decide whether a given lesion is cancer or benign ulcer. Pack and Livingston<sup>18</sup> state "If every patient with gastric cancer entered the best surgical clinic in the world, 95 per cent would remain uncured and approximately 90 per cent would be dead of the disease in 18 months." Without earlier diagnosis the salvage rate cannot be improved.

In 1946 Papanicolaou<sup>2</sup> reported 9 cases in which the aspirated gastric secretion was studied for cancer cells. Two of the patients had carcinoma. A cytologic diagnosis of cancer was made in both.

In the Vincent Memorial Laboratory gastric fluid in 50 cases has been examined. Twenty-four of these patients had cancer of the stomach. Cancer cells were recognized in the gastric secretion of 15. One case with a benign lesion was mistakenly called malignant. Cancer cells were found in 2 cases in which the excised stomach showed no gross evidence of neoplasia. Histologically both were diagnosed as preinvasive carcinoma. Of the 5 early cases of gastric carcinoma studied, cancer cells were found in the gastric fluid in 4. In 1 case, except for the cytologic report, cancer was totally unsuspected—preoperatively, at operation and on examination of the gross specimen. The application of cytologic examination to the diagnosis of early gastric cancer is now being investigated in the Vincent Memorial Laboratory.

### SUMMARY

The cytology of various body fluids has been studied as a means of cancer diagnosis. The value of the method for the diagnosis of uterine carcinoma has been established. In the detection of early cervical neoplasms, it is apparently more accurate than routine biopsy. Studies are in progress to determine the efficacy of cytologic examination in the diagnosis of cancer of the stomach, lung and urinary tract. In the early diagnosis of gastric carcinoma the new method may prove to be of great value.

## RECENT THERAPEUTIC TRENDS IN ALLERGY\*

WALTER S. BURRAGE, MD†

DUSTON

TWO topics of current interest in allergy are considered in this study: the present status of histamine, with particular reference to the new antihistaminic drugs, and the role of inhalation therapy, including the aerosols.

It would be satisfactory to be able to report that recent advances in allergy have made clear an understanding of the fundamental characteristics of the allergic state. It is true that investigators are gradually learning more about the trigger mechanism that sets off the explosion, but unfortunately they are still ignorant of the nature of the charge with which the allergic gun is loaded. The chief constituent of this ammunition has long been supposed to be histamine. Study of this assumption has led to much investigative work over a period of years as well as to the development of several antihistaminic agents of clinical value. Feinberg<sup>1</sup> has reviewed this subject in an excellent article. A few points are worthy of emphasis, since they demonstrate the results of efforts to counteract the effects of this drug, whose role is presumed to be so important in the mechanism of the allergic reaction, particularly in the type associated with the immediate skin reaction and the production of edema and hyperemia.

As early as 1910, Dale and Laidlaw<sup>2</sup> called attention to the similarity of the action of histamine and the manifestations of anaphylactic shock in animals. In 1927 Best and his associates,<sup>3</sup> in demonstrating that histamine is normally present in many tissues, led the way to an explanation of its sources in the body. Variations in anaphylactic reactions in several species of animals were later considered to be due to varying concentrations of histamine in different organs.

In allergy in human beings, however, the importance of the role of histamine has not been so clearly

shown, but has been inferred more from certain similarities observed between anaphylaxis in animals and allergic reactions in man and by the fact that histamine administered to man produces some if not all of the phenomena observed in clinical allergy. Investigation of the systemic effects of histamine led Weiss and his co-workers<sup>4, 5</sup> to observe that vital capacity was decreased and that attacks of wheezing were frequently produced in patients with asthma after the administration of histamine. Daurehande et al.<sup>6</sup> further demonstrated the bronchoconstrictor properties of choline and histamine when employed as aerosols in human subjects. These observations were confirmed by Curry,<sup>7</sup> who pointed out that, whereas normal subjects showed no reduction in vital capacity after the administration of histamine, those with asthma did so if this drug was given by either the intramuscular or the intravenous route and, to a less extent, when it was administered under the tongue or by nebulization. Encouraging results have likewise been obtained by Curry<sup>8</sup> in a study of the effects of various drugs, including the antihistaminic agents, when he succeeded by their use in preventing or modifying changes in vital capacity after exposure to aerosolized extracts.

Treatment directed toward the histamine theory has taken several forms: immunization by treatment with histamine itself or histamine conjugate (hapamine), destruction by a ferment, such as histaminase, and inhibition or neutralization by the antihistaminic drugs.

Each of these methods of treatment has been tried. Desensitization by repeated injections of histamine has been widely attempted in allergic conditions in an effort to increase tolerance to this agent. The results of this type of therapy have been disappointing, and it is now concluded by most observers that such injections do not actually increase a subject's tolerance to histamine or significantly

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1947.

modify his own particular reaction to a given dose of this drug

Histamine azoprotein, a histamine conjugate, has also been employed on the grounds that it might more readily stimulate antibodies than histamine

FIGURE 1 (*N'*-phenyl-*N'*-benzyl-*N*-dimethylethylenediamine) Antergan

itself, but this has also failed to produce consistent enthusiasm<sup>1</sup>

Histaminase provided what at first seemed a logical approach to a fundamental problem since this enzyme was proved capable of destroying histamine in many cases in vitro. In man, however, it did not produce comparable results so that even its dis-

FIGURE 2 (*N*-*p*-methoxybenzyl-*N*-dimethylaminoethyl  $\alpha$  aminopyridine) Neoantergan

coverer, Best,<sup>9</sup> had to admit after ten years of trial that there was no physiologic basis on which to rest its clinical use

The development of the antihistaminic drugs constitutes the most recent and by far the most successful attack upon the effects of histamine. In contrast to attempted desensitization against histamine or

FIGURE 3 (*Beta*-Dimethylaminoethyl Benzohydril Ether Hydrochloride) Benadryl Hydrochloride

its destruction by enzymic action, these drugs produce their effect by neutralizing histamine by competitive chemical action. It may also be mentioned as a matter of contrast, that epinephrine, ephedrine and the other sympathomimetic drugs act in an entirely different manner—namely, by vasoconstriction. This distinction is of particular clinical importance, since it means that both types of drugs may be used together without mutual interference

After extensive trials with various compounds that had been shown to possess histamine-inhibiting properties, experimental observations with two antihistaminic drugs were reported in France. Halpern,<sup>10</sup> described antergan in 1942, and Bovet and his associates<sup>11</sup> neoantergan in 1946. Both drugs are effective. The latter, which is less toxic than antergan, shows particular promise.

Benadryl and Pyribenzamine, the new American histamine antagonists, have had more extensive clinical trial than the French compounds and are now generally accepted as of proved value in the treatment of certain increasingly clearly defined manifestations of allergy.

The structural formulas of these four compounds show their close chemical similarity (Fig 1-4).

Reports regarding the assets, liabilities and comparative merits and demerits of Benadryl and Pyn-

FIGURE 4 (*N'*-pyridyl-*N'*-benzyl-*N*-dimethylethylenediamine) Pyribenzamine

benzamine have flooded the literature. This paper is not concerned with summarizing these varying statistics but points out the conditions in which it is generally agreed that they are of value and to warn against their frequent side actions. Benadryl and Pyribenzamine are of greatest value in providing temporary relief in urticaria, angioedema and hay fever, in manifestations of serum disease, in the reactions due to penicillin or the sulfonamides and in the itching from atopic and contact dermatitis. They are less effective in perennial vasomotor rhinitis and even less so in asthma, particularly in cases of infectious or intrinsic etiology.

Side actions are frequent in both, the commonest of these being sedation and drowsiness. Vertigo, palpitation, nervousness, insomnia and gastric irritation appear less often. These occurrences sometimes become less marked after the first few doses, but they occasionally persist and necessitate discontinuance of the medication. The disadvantage of sedation may sometimes be converted to an asset when insomnia or anxiety complicates the picture, especially during the night or by day in cases of pruritus. Benzedrine may be of value in counteracting this drowsiness. There is a certain amount of selective response to these two antihistaminic agents in individual patients, both from the standpoint of therapeutic effect and in the appearance of side reactions.

An average dosage of 50 mg of either drug after meals and at bedtime is commonly sufficient to con-

tol symptoms, but this must be varied both in time and amount of administration in accordance with the patient's tolerance. The daily dose may be increased to 400 mg or over, in the absence of reactions, if necessary to obtain a clinical response.

It must be emphasized that these drugs do not immunize the patient, nor is their benefit more than a brief one, lasting but a few hours after each dose.<sup>12</sup> No evidence has been presented that they interfere with the mechanism of the production of immunity or that their prolonged and widespread administration is followed by remote toxic effects, but it is as yet too early for final judgment on these points.

The new antihistaminic agents are valuable adjuncts to the treatment of allergic disease, as epinephrine and ephedrine have been for some years. They do not minimize the importance of hyposensitization or of management by a carefully conceived and executed program, but when combined with other established methods of treatment, they do offer many allergic patients an increased chance of relief.

Inhalation therapy has made remarkable progress in recent years in the control of respiratory disease including bronchial asthma. Various therapeutic agents and methods have been introduced, particularly by Barach,<sup>13,14</sup> Segal<sup>15</sup> and others. The more notable advances have been the use of oxygen, mixtures of oxygen and helium and positive-pressure therapy, including the employment of therapeutic aerosols. Patients with severe asthma often respond to oxygen under normal pressure. If this fails, one should turn to oxygen or oxygen mixed with helium, preferably under positive pressure in both phases of respiration. The latter form of therapy can be administered with a Barach hood apparatus. If this is not obtainable, an O.E.M. mask, readily available to all physicians, may be used to supply positive pressure in the expiratory phase of respiration alone. Segal<sup>15</sup> recommends that positive-pressure therapy be carried on intermittently, for it may be tiring to the patient with uninterrupted administration, and he has further demonstrated that this form of therapy provides one of the most valuable methods in the treatment of severe bronchospasm.

Various therapeutic aerosols have been utilized for the management of certain phases of bronchial asthma. The bronchodilator drugs—epinephrine in a strength of 1:100 and vaponephrine and isuprel<sup>16</sup> (an isopropyl amino-ethanol)—have been found to be most effective for this purpose. A mixture of equal parts of 1 per cent Neo-Synephrin and any one of the above bronchodilators may occasionally prove of even greater value, since Neo-Synephrin, though a poor bronchodilator, is an effective broncho-vasoconstrictor.

The necessity for an efficient nebulizer must be emphasized. It is essential that the average mass diameter of the aerosolized particles be in the neighborhood of 1 to 3 microns to ensure their transit

into the lower respiratory passages and to prevent them from being deposited upon the mucous membranes of the upper respiratory tract. Most of the pioneer investigators in this field have found the vaponephrine nebulizer adequate for this purpose.<sup>16,17,18</sup>

Antibiotic aerosols, particularly penicillin, have more recently proved of benefit in many respiratory diseases, such as lung abscess, bronchiectasis, acute laryngotracheobronchial edema and purulent sinus disease.

Numerous reports in the recent literature, both favorable and unfavorable, have presented over-all results of penicillin therapy in bronchial asthma by the intramuscular, oral and aerosol routes.<sup>19-24</sup> On the whole, these have been disappointing except in cases in which there has been complicating purulent infection. When such a condition has been treated in the sinuses, favorable results in a small series of cases have been reported by Barach and his associates<sup>25,26</sup> with specially adapted equipment developed for the purpose. This consists of a negative-pressure sinus apparatus by which the nasal inhalation of penicillin aerosol is employed in conjunction with a scheme for interrupted negative pressure applied to the nasal passages. When this pressure returns to normal, penicillin is aspirated into the sinus cavities.

In the so-called "intrinsic cases" or in bacterial asthma, it might be thought that penicillin would often control the etiologic process and thereby arrest the disease, particularly when the drug can be concentrated locally in the pulmonary tissues, as penicillin aerosol can. In some cases, the penicillin-susceptible organisms can be eradicated in this way,<sup>21</sup> but the clinical course of the asthma is usually unaltered or is only temporarily improved. It should also be remembered that allergic reactions to penicillin, including the aerosol, are being encountered with increasing frequency, particularly in asthmatic subjects.<sup>27-29</sup>

Care must be exercised in the appraisal of the therapeutic efficacy of any procedure in bronchial asthma. The clinical picture may be modified by many factors other than the one under immediate consideration. Among these is the tendency for intrinsic asthma to exhibit seasonal fluctuations, improving in warm weather and becoming worse with recurrent infections in the winter. Hospitalization itself, with its change of environment, provides multiple factors of a therapeutic nature, both medicinal and psychologic, that often bring about a remission, as does the careful control of previously unrecognized extrinsic allergens or of structural abnormalities. Penicillin should therefore be considered as a therapeutic agent for the treatment of clear-cut infectious processes and not as a routine procedure in the therapy of bronchial asthma.

Brief mention should be made of promising results obtained after the recent employment of aero-

sols for the purpose of testing asthmatic patients who have failed to react to suspected pollens by routine skin tests. Lowell and Schiller<sup>30</sup> have exposed such patients to the inhalation of various pollen extracts, recording the resulting effect upon their vital capacities. These authors have been able to demonstrate that substances that produce a fall in vital capacity are of clinical significance as judged by the histories and by the production of mild asthma characteristic of the seasonal attacks.

### SUMMARY

The modern concepts of the possible role of histamine in the mechanism of the allergic reaction are discussed. It is pointed out that treatment with histamine or with histamine azoprotein does not give adequate clinical evidence of increased human tolerance to histamine and that the enzyme histaminase is not capable of destroying histamine in vivo. The new antihistaminic drugs, which apparently operate by competing with the liberated histamine in their attachment to the receptor cell, have been more successful in treatment. The temporary nature of their action, their advantages and their disadvantages are reviewed.

Recent advances in inhalation therapy for asthma are described, including the use of therapeutic gases, both with and without positive pressure, and the administration of various therapeutic aerosols. A new method is pointed out by which aerosolization may be utilized for further investigation of the action of drugs of potential value in allergy and for the study of cases of asthma of inhalant origin refractory to better known methods of testing. The limitations of penicillin in the treatment of chronic asthma are set forth.

Allergic symptoms are potentially recurrent and may appear in varying forms dependent upon the changing location of the shock organ. They are the manifestations of a chronic, constitutional inherited disorder, the exact nature of which is still unknown. No one method of therapy or agent that will afford more than temporary relief once these symptoms have appeared has yet been discovered, nor can it be instrumental in controlling the precipitating factors that lead to the appearance of manifestations recognized as allergic disease. For this reason it is strongly recommended that the new drugs and procedures outlined above, as well as all others that have been introduced to date, be employed, not as isolated methods of therapy but as supplementary aids to already well established principles of treatment. There is as yet no short cut

and no substitute for sound allergic management, which includes prolonged observation and education of the patient in conjunction with elimination and desensitization when these procedures are indicated.

SEPTICEMIA DUE TO *PROTEUS VULGARIS*\*

## Review of the Literature and Report of a Case Cured by Streptomycin

HERBERT L. ABRAMS, M D †

BROOKLYN, NEW YORK

THE term *Proteus vulgaris* (*Bacillus proteus*) refers to a number of different species of a gram-negative, actively motile rod form originally described in 1895.<sup>1</sup> These organisms characteristically exhibit the "swarming" phenomenon in colonies on agar. They are widely distributed in contaminated soil and sewage and are found on the skin, in the urine and in the mouth.<sup>2</sup>

The *Proteus* organism was at first thought to be nonpathogenic, but Larson and Bell<sup>3</sup> established its pathogenicity for rabbits, rats and guinea pigs in 1915. It has since been implicated in a large number of pathologic states, though its usual status is that of a nonpathogen and it is found in a high percentage of normal stools.<sup>4</sup>

*Proteus* septicemia is a relatively rare condition. Cragg<sup>5</sup> stated in 1941 that 13 cases had been recorded in the literature. McKee<sup>6</sup> reviewed *P. vulgaris* infections in 1944 and found 23 cases of septicemia produced by foci of infection other than the genitourinary tract. Data on 52 reported cases<sup>5-13</sup> are presented below, together with a report of a case cured by streptomycin therapy.

## AGE, SEX AND SOURCE

The youngest reported case was in a nine-day-old infant,<sup>9</sup> and the oldest in a seventy-five-year-old man.<sup>10</sup> Between these two extremes, the cases were distributed generally among all decades, with the exception that a larger proportion of cases were in the third decade. Of the patients who were under forty, roughly four fifths had middle-ear infection, and of those over forty, about four fifths had primary genitourinary-tract disease.

About 75 per cent of the patients were male and 25 per cent female.

Of 47 cases in which the source of the septicemia was established, 21, or 44.7 per cent, originated in the ear, nose or throat, 22, or 46.8 per cent, originated in the genitourinary tract, and 4, or 8.5 per cent, derived from miscellaneous foci.

Among the cases associated with genitourinary-tract infection, 7 followed directly the use of instrumentation (catheterization or cystoscopy) and 8 were caused by major operations of the genitourinary tract—5 after prostatectomy and 1 each after suprapubic cystostomy, nephrostomy and nephrolithotomy. Two cases were associated with pyelonephritis,

and 1 each with cystitis, pyelitis, renal tuberculosis, carcinoma of the bladder and cord bladder.

The source of infection in the 21 cases involving the ear, nose and throat was the middle ear in 18, the tonsils in 2 and a questionable pharyngeal ulcer in 1 case.

The remaining 4 cases were associated with a suppurative ovarian cyst, a lung abscess, a war wound and meningitis in a nine-day-old infant.

## PATHOLOGY

Few detailed pathological reports are available. Characteristically, all infected areas exhibited a foul-smelling, green or brownish-green pus. Lung abscesses containing the typical foul pus were found in 6 of 9 cases in which autopsy findings were reported. Isolated findings included septic thrombosis of the inferior vena cava, lateral sinus thrombosis, thrombophlebitis of the renal veins, congestion of the spleen, brain abscess, purulent meningitis from *P. vulgaris*, pyelonephritis, osteomyelitis and chronic otitis media. The microscopical pathology was not distinctive, an outpouring of polymorphonuclear leukocytes being most characteristic.

## CLINICAL PICTURE

In most cases, the patients appeared acutely ill and ran a high, spiking fever with chills and a septic course. Occasionally a typhoid type of fever curve was seen, and some cases diagnosed as typhoid fever came to post-mortem examination. Anemia was present in some cases, and leukocytosis in almost all. White-cell counts ranged from 8700 to 35,000, with an average level of 12,000 to 16,000. The differential count showed from 70 to 84 per cent neutrophils.

When recovery took place, the illness was usually of many weeks' duration. In cases in which operative procedures preceded infection, recovery, when it occurred, was more rapid.

Division of the cases into two groups based on the source of the infection—the ear and the genitourinary tract—establishes the symptomatology associated with most cases. In those deriving from the ear, a history of chronic otitis was almost invariable, and associated pain and discharge were present. In those related to the genitourinary tract, the history of previous operative procedures was present in 15 of 22 cases, and typical symptoms of urinary-tract disease with concomitant chills and fever were noted.

\*From the Department of Medicine, Long Island College Hospital.

†Assistant resident in medicine, Montefiore Hospital, New York City; formerly in the Department of Medicine, Long Island College Hospital.

### PROGNOSIS

In 48 cases in which the subsequent course was described, 31 patients, or 64.6 per cent, died, and 17 patients, or 35.4 per cent, recovered. The prognosis was far better in the cases deriving from the genitourinary tract than in those deriving from the ear, nose and throat. In the former group, the mortality was 36.8 per cent, whereas in the latter group it was 80.1 per cent.

### DIAGNOSIS

The diagnosis can be established only by obtaining a positive blood culture for *P. vulgaris*. When positive blood cultures are obtained, investigation of the two main foci of infection is imperative.

### CASE REPORT

A 44-year-old man entered the hospital with a chief complaint of chills and fever of 3 weeks' duration.

He had previously been admitted to the hospital seven times since 1932 for recurrent renal calculi, but on each occasion he had been able to pass the stones without operative intervention. The last previous admission had occurred 5 months before the present illness. At that time, the patient passed eight small calculi and one large calculus. After cystoscopy, he developed a shaking chill and fever, and during the week following discharge from the hospital, he had three episodes of chills and fever. One month after discharge, he began to notice moderate shortness of breath on exertion and at that time was told that he had a heart murmur. Three weeks before the present admission, he began to have recurrent episodes of shaking chills and fever at about 9 o'clock each evening. He was placed on sulfonamides and remained afebrile for a few days, only to have a recurrence of the chills and fever. Sulfonamides were discontinued, and penicillin therapy initiated, but the penicillin failed to influence the course. The patient was then hospitalized.

Physical examination revealed the presence of marked generalized pallor, slight cardiac enlargement, and a loud, harsh, apical systolic murmur heard throughout systole and masking the first sound. No other positive physical findings of note were observed.

On the afternoon of admission, the temperature was normal, but it rose to 103°F in the evening, after a shaking chill.

Examination of the blood showed a hemoglobin of 9 gm and a white-cell count of 10,000 to 12,000, with 74 per cent neutrophils, 20 per cent lymphocytes, 4 per cent monocytes and 2 per cent eosinophils. The hematocrit was 28 per cent, and the corrected sedimentation rate 30 mm in 1 hour (Wintrobe method). The blood sugar was 109 mg, and the blood urea nitrogen 22.1 mg per 100 cc. The total protein was 7.5 gm per 100 cc, with an albumin of 4.1 gm and a globulin of 3.4 gm. The icteric index was 6.0, the blood calcium was 10.6 mg and the phosphorus 3.5 mg per 100 cc, and the alkaline phosphatase 4.5 units per 100 cc. The urine had a specific gravity of 1.024 and contained a trace of albumin, with 10 white cells per high-power field in the sediment and a negative Sulkowitch test.

Blood cultures were taken, and on the 6th day after admission, a pure culture of *P. vulgaris* (15 colonies per cubic centimeter) was reported. At the same time, a pure culture was found in the urine. Positive blood cultures were again obtained during the next 2 days, and the patient was then placed on streptomycin, 0.3 gm every 3 hours. He remained on streptomycin for 10 days, receiving a total of 25 gm. No positive blood or urine cultures were obtained after the initiation of streptomycin therapy. After the 1st day of treatment, the patient had no more chills, and the temperature never went above 101°F. After a week of normal temperature, he was discharged and has remained well ever since.

### DISCUSSION

From the review of the literature presented above, it is apparent that *Proteus* septicemia formerly had

a high mortality. That the prognosis was worse in cases associated with disease of the ear, nose and throat was probably due to the long-standing and deep-seated infection that led up to the septicemia.

Therapy, until the advent of streptomycin, was varied and not demonstrably the direct cause of cure. Surgery was utilized in 9 patients. Of 6 patients on whom mastoidectomy was performed, all died. Two of 3 patients on whom nephrectomy was performed survived. Recovery followed bacteriophage in 1 case<sup>40</sup> and vaccine in 2 cases,<sup>10, 18</sup> and sodium ricinoleate therapy was followed by recovery in 1 case.<sup>40</sup> Sulfonamides were used in 3 cases, 2 of the patients died,<sup>43, 44</sup> and 1 survived.<sup>6</sup>

In the National Research Council Report on streptomycin<sup>46</sup> 5 cases successfully treated with streptomycin were noted. No data were obtainable in these cases. The case presented above illustrates further the striking effect of streptomycin on the *Proteus* organism. This effect has been demonstrated experimentally in the chick embryo,<sup>47</sup> and in disease of the genitourinary tract, good therapeutic results have been obtained.<sup>48</sup> Thus, a sharp reduction in the hitherto high mortality may be expected in the future.

### SUMMARY

Data on 52 cases of septicemia due to *Proteus vulgaris* reported in the literature are presented. These cases fell into two main groups: those associated with genitourinary-tract disease, and those associated with infection of the ear, nose and throat. Until the advent of streptomycin, the prognosis in these cases was poor.

A case cured by streptomycin is presented, and it is suggested that a striking reduction in mortality may be expected.

## MEDICAL PROGRESS

### EPIDEMIOLOGY OF TULAREMIA IN MASSACHUSETTS WITH A REVIEW OF THE LITERATURE

JOHN C. AYRES, MD,\* AND ROY F. FEEMSTER, MD, DR. PH.D.

BOSTON

ALTHOUGH tularemia is considered a "truly American disease," Ohara<sup>1</sup> refers briefly to a historical account of a disease that he thinks was tularemia, described in 1837 by a Japanese physician, K. K. Homma.<sup>2</sup> Ohara states that Homma, under the heading of intoxication of rabbit meat, described in detail the incubation period and symptoms of a disease that, according to Homma, had not theretofore been described. After tularemia became known in America, physicians in the West claimed to have seen similar cases as early as 1907 in Arizona and 1909 in Missouri.

In 1911 McCoy<sup>3</sup> contributed the first information of the etiology of this disease by his discovery of what he called "plague-like disease of rodents" prevalent among the California ground squirrels,

first observed in squirrels received from Tulare County, California. McCoy and Chapin,<sup>4,5</sup> in 1912, discovered the causative organism of the disease in the California ground squirrels and named it *Bacterium tularense*,<sup>6</sup> after Tulare County. McCoy and Chapin,<sup>4,5</sup> in 1912, also reported complement fixation and agglutination of *Bact. tularense* by the serum of Chapin and a laboratory attendant, both of whom were extensively engaged in handling or dissecting infected rodents in the San Francisco laboratory and constituted the first cases of laboratory infection in man.

In Utah a disease of man was for several years popularly known as "deer-fly fever," owing to the belief that the infection was caused by the bite of the bloodsucking fly, *Chrysops discalis*, commonly found on horses. This belief found expression in a paper read before the Utah State Medical Association, Salt Lake City, on October 3, 1910, by

\*Epidemiologist, Division of Communicable Diseases, Massachusetts Department of Public Health.

†Director, Division of Communicable Diseases, Massachusetts Department of Public Health.

‡Now more technically called *Paratuberculosis tularenis*.

Pearse,<sup>6</sup> of Brigham City, Utah. Pearse's cases constitute the first reported human cases of tularemia differentiated clinically, although the disease was not demonstrated to be tularemia until 1919.

Vail,<sup>7</sup> Sattler<sup>8</sup> and Lamb,<sup>9</sup> three ophthalmic surgeons of Cincinnati, Ohio, each reported a case of "conjunctivitis tularensis" in 1914, 1915 and 1917, respectively, in persons who had dressed rabbits and in whom the seat of primary localization was the conjunctival sac. The bacteriologic diagnosis of these 3 cases was made by Wherry and Lamb,<sup>10</sup> who isolated *Bact tularensis* on a culture medium from guinea pigs into which the eye scrapings had been injected. Vail's case is the first human case of tularemia on record to be diagnosed bacteriologically. Wherry and Lamb<sup>11, 12</sup> also isolated the organism from two wild cottontail rabbits found dead and collected in southern Indiana near the residence of Sattler's patient. This isolation from wild rabbits was the first bacteriologic proof of the rabbit reservoir of infection.

Francis,<sup>13, 14</sup> investigating "deer-fly fever" in Utah in 1919, recognized the identity of the Utah disease among human beings and the California ground-squirrel disease, and named the disease tularemia on account of the presence in the blood of the causative organism. He furnished proof of this identity by isolating *Bact tularensis* from 7 fly-bitten human patients, from 17 wild jack rabbits and from a ground squirrel, by demonstrating anti-tularensis agglutinins in his own blood and that of his assistant, both of whom had contracted the disease in the field laboratory, and by transmitting the infection among laboratory animals by the deer-fly, *Chrysops discalis*.<sup>15</sup>

Parker, Spencer and Francis,<sup>16</sup> of the United States Public Health Service, in the course of their studies of Rocky Mountain spotted fever at Hamilton, Montana, recognized the agency of the common wood tick of Montana, *Dermacentor andersoni*, as a host and transmitter of tularemia.

Dr J. Lawn Thompson,<sup>17</sup> of Washington, D. C., was the first to recognize a case of tularemia in the eastern United States when he made the diagnosis in a market man who was engaged in skinning and dressing wild rabbits in the Washington market in November and December, 1921. Francis<sup>18</sup> isolated virulent *Bact tularensis* from seven of 914 rabbit livers examined in the Washington, D. C., market in January, 1923.

Four articles in Japanese text, dealing with a disease of man occurring in Japan, were proved by Francis and Moore<sup>19</sup> to have been tularemia, although none of the articles contained specific mention of tularemia or of the published work of the American investigators on the disease. Two of these articles were by Ohara,<sup>1, 20</sup> one by Aoki, Kondo and Tazawa,<sup>21</sup> and one by Iwamoto, Muto and Aomura.<sup>22</sup> The dates of publication were between March 12, 1925, and July 10, 1925. Proof of the identity of

the American and Japanese diseases was furnished by Moore and Francis,<sup>19, 23</sup> who, on seeing Ohara's first descriptions, requested material from Ohara and demonstrated complete serologic and bacteriologic proof of the identity of the Japanese disease and tularemia of the United States.

Since the original discovery by McCoy in 1911, tularemia as an endemic disease of man has been observed in the forty-eight states, the District of Columbia and Alaska, it has been reported from Canada, Japan and the Soviet Union and, in recent years, in epidemic proportions from Europe (Sweden, Norway, Bohemia, Austria, Turkey and Germany).

### MODES OF TRANSMISSION

Tularemia is primarily a disease of certain rabbit-like mammals (Order *Lagomorpha*) and occasionally of certain rodents (Order *Rodentia*) and other wild mammals (shrew, opossum, beaver, coyote, red fox, gray fox and so forth) and game birds (sage hen, quail and grouse). A recently published list of vertebrates known to be naturally infected with tularemia includes, for the United States and Canada, six species of birds and twenty-eight species of mammals.<sup>24</sup> Although the disease is readily transmissible to man, human infections are only accidental. After recovery, one attack confers lifelong immunity.

### Contact

Human infections may be acquired from three main sources<sup>25</sup> the most common method, in eastern North America particularly, being by contact with a diseased animal. The bacteria may enter the human skin, which may be abraded or possibly even intact, or the mucous membrane (particularly that of the eyes) during the skinning and dressing of infected wild animals or while their skins are being handled. Thorough cooking kills the organism, however, infection may occur from eating raw or improperly cooked infected meat.<sup>26</sup> The disease has been known to be conveyed to people by the bite or the scratch of some infected animals. Self-inoculation by contact is prevalent among hunters, cooks and butchers, and there are often cases in large cities in which so-called "market fever" is well known among marketmen. Infection by contact is most frequent from November to January, during the hunting season, when cottontail rabbits, particularly, are for sale. Dogs and cats are susceptible, and have been known to contract the disease by eating raw meat of sick wild rabbits. In dogs, *Bact tularensis* may persist for many days without any outward symptoms.<sup>27</sup> Although the domestic rabbit is susceptible to experimental tularemia, rabbits raised in rabbitries have very rarely been found infected in this country and therefore may be handled and eaten with safety.<sup>28, 29</sup>

### Ticks

Tularemia is usually transmitted among wild mammals and birds by infected ticks, either by the bite or, more probably, by the feces that the ticks void while engorging on the host. Several species of ticks are known as natural or potential vectors. The rabbit tick, *Haemaphysalis leporis-palustris*, one of the most common ticks, has been found infected in nature<sup>10</sup> and transmits the disease in the laboratory.<sup>11</sup> Infected female ticks also pass on the bacterium to their eggs and larvae.<sup>12</sup> *H. leporis-palustris* is a particularly active transmitter, since all stages — larvae, nymphs and adults — occur often in unbelievable numbers on wild *Lagomorpha*, the adults being restricted to this type of host. Larvae and nymphs, however, often attach themselves also to migratory game birds, which may thus carry infected ticks over long distances and into new territory. It seems probable that *Bact. tularensis* survive the winter chiefly in infected *H. leporis-palustris*, which have been dropped off from infected cottontail rabbits dying of the disease.<sup>13</sup> All stages of this tick hibernate away from the host. The rabbit tick is not known to attack man and, therefore, is not instrumental in the transmission of tularemia from infected animals to human beings. The Rocky Mountain wood tick, *D. venustus* (Banks)\* is infected in nature in Montana.<sup>14,15</sup> It has also been proved that this tick is a true biologic host of *Bact. tularensis*, which it harbors not only in its feces but also in the epithelial cells of the digestive tract and malpighian tubes and in the celomic fluid. Furthermore, an infected female *D. venustus* will transmit *Bact. tularensis* to a certain percentage of its eggs, larvae and nymphs.<sup>11</sup> The presence of tularemia in the Pacific coast wood tick, *D. occidentalis* Currie, was demonstrated in California.<sup>16</sup> The eastern wood tick, *D. variabilis*, was found infected with the disease in nature, notably in Minnesota, by Green.<sup>17</sup> According to Philip and Jellison,<sup>18</sup> in this tick the bacteria may also be transmitted by an infected female to part of the progeny, through the eggs. However, in later investigations by Bell<sup>19</sup> no hereditary infection could be obtained, and it was concluded that such transmission appears to be of no significance for *D. variabilis*. Bell pointed out that the lack of difficulty of hereditary infection of the tick may be a most important limiting factor in the epizootic course of tularemia. He also demonstrated that infected *D. variabilis* feeding on immune or normal hosts lose their infection, presumably owing to the stimulating effect of the blood meal upon a normal bacteriocidal function of the ticks' gut. Before losing their infection as a result of feeding, such infected ticks may nevertheless inoculate a normal host, which will later on be a source of infection to other ticks feeding upon it. On the other hand, when fed upon an immune host, infected

ticks will not infect it, so that such an animal will not transmit the disease further to clean ticks. The number of animals that have become immune by a previous mild or chronic infection in a given area may also be of importance in limiting the spread of tularemia.

Wild rabbits and hares and their ticks are one of the most serious health problems, these animals being often infected with tularemia. Because many of them are handled by hunters, farmers, marketmen and consumers, they are a main source of human infection. All *Lagomorpha* are susceptible to the disease.<sup>20</sup> The snowshoe hare (*Lepus americanus*), the jack rabbit (races of *Lepus californicus*) and the cottontail rabbit (*Sylvilagus floridanus*) have all been found infected in nature. Among the *Lagomorpha*, tularemia is transmitted almost exclusively by *H. leporis-palustris*, rabbits and hares are the only efficient breeding host of this tick. The extent to which the larvae and nymphs of *D. variabilis* infect rabbits and hares in eastern North America is imperfectly known, however, some rodents, particularly the meadow mouse (*Microtus pennsylvanicus*), are the chief hosts of the larvae and nymphs of *D. variabilis*. The abundance of meadow mice is often closely correlated with the prevalence of *D. variabilis* in a given locality, such as the Cape Cod area and the neighboring islands. Little is known, as yet, concerning the natural occurrence of tick-borne diseases in the northeastern United States.

In the northeastern United States some human cases seem to have been caused by the adults of *D. variabilis*, which must have become infected in the immature stages, on wild life, but tick-borne infection of man is possible only when wood ticks are active, particularly from March to August.

### Other Bloodsucking Insects

The third method of transmission involves a variety of bloodsucking insects, such as the squirrel flea (*Ceratophyllus montanus*), the rabbit louse (*Haemodipsus ventricosus*), the squirrel louse (*Neohaematopinus laevisculus*), two western species of deer flies (*Chrysops discalis* and *C. nortyi*), some western species of horseflies (*Tabanus*), the stable fly (*Stomoxys calcitrans*), a species of the black fly (*Simulium kaimai*) and several species of mosquitoes (*Aedes aegypti*, *Aedes cinereus* and others). With all these insects, transmission has been effected under laboratory conditions from sick to healthy animals, either mechanically by the bite (interrupted feeding) or by the feces.<sup>21,22</sup> Such experiments do not, however, necessarily incriminate these insects as effective transmitters of the disease under natural conditions. In the northeastern United States, although several species of *Chrysops* are abundant and often attack people during the summer, they have been seldom incriminated in human cases of tularemia.

\*The same species as *D. andersoni* (Stiles).

### *Ingestion of Food and Water*

In recent years, a fourth possible source of infection has come to light—namely, drinking water contaminated by infected animals, particularly muskrats and beavers<sup>40-42</sup> Schuller and Erdman<sup>43</sup> describe an epidemic occurring in Germany during the summer of 1942, when 100 cases of tularemia were ascribed to the Dnieper River water and food in the township of Tchirin contaminated by mouse and rat excreta Khatenever,<sup>44</sup> in 1943, described an epidemic in Russia in which many patients were

occurring in central Russia that were due to threshing ricks contaminated by infected rodents Infection occurred by the inhalation of dust, giving rise to the typhoidal and pneumonic forms of the disease Similar epidemics are described by other Russian writers<sup>44, 47</sup>

### TULAREMIA IN MASSACHUSETTS

Prior to 1937 only 3 cases of tularemia in human beings were reported in Massachusetts, and it was definitely ascertained that these infections had their origin outside the Commonwealth However, in

TABLE 1 *Cases of Tularemia Reported in Massachusetts from 1929 to 1947*

CASE No	AGE yr	SEX	LOCALE	TIME	METHOD OF TRANSMISSION	INCUBATION PERIOD days	TYPE OF LESION	LABORATORY CONFIRMATION
1	48	M	Boston <sup>48</sup>	December, 1929	Skinning of rabbit from Illinois	3	Ulceroglandular (right index finger and arm)	Agglutination 1 640
2	—	M	Cumberland Island (off Florida) <sup>41</sup>	March, 1929	Wood tick or deer fly	?	Ulceroglandular	Agglutination 1 1280
3	32	M	Colorado	May, 1934	Handling or eating of wild rabbit	4	Glandular (? septicemic and pneumonic)	Agglutination 1 1280, Foshay skin test positive

infected through eating and drinking material contaminated by infected field and house mice

Randerath<sup>45</sup> makes a reference to the origin of an outbreak among human beings during the winter of 1942-1943 on the eastern German front, where there had been an increase the previous autumn in field mice that had become infected from water rats When, at the onset of cold weather, the troops were housed, they came into contact with the mice, and cases of tularemia occurred He believed that food and water may have been the vehicles of transmission

### *Inhalation*

Another source of infection recently uncovered is inhalation Maisky,<sup>46</sup> in 1945, wrote of epidemics

1937 the first case of human tularemia definitely contracted in the Commonwealth was reported from Falmouth Since that time a total of 14 cases have been reported, 6 of these occurring in the last two years Furthermore, 8, or 57.2 per cent, of the cases have occurred on Cape Cod, 3 more, or 21.4 per cent in Plymouth County, which is adjacent to Cape Cod, and the remaining three, or 21.3 per cent, in the eastern part of the Commonwealth (Waltham, Georgetown or Amesbury and Boston) The ages varied from three to sixty-eight years, 6 female and 8 male patients being afflicted All patients recovered except 1 man (Table 1, Case 13), who died nine months after contracting the disease The type of disease varied, 7 patients having the ulceroglandular type 4 the pneumonic, 2 both ulceroglandular and

pneumonic, and 1 typhoidal. The diagnoses were confirmed by positive agglutination tests, which showed a maximum rise in titer, on the average, by the third week varying from 1:320 to 1:2560 in all but 2 of the cases. In 1 case (Table 1, Case 9), *Bact tularensis* was isolated from the pleural fluid after passage through guinea pigs and mice. The incubation period on the average was within seven days of exposure.

It is interesting to note that 8, or 57.2 per cent, of the patients were definitely ascertained to have been bitten by ticks, and 2 were probably bitten by ticks. Contact with rabbits was definitely established in 2 cases, contact with a dog that was infested with ticks and later manifested a positive agglutination for tularemia, with a titer of 1:40, was responsible for another case (Table 1, Case 4). In another case (Case 13) the source of infection could not be ascertained, except that it was probably by contact because the illness began with an infection of the thumb, pulmonic involvement eventually occurring. Furthermore, the patient worked as a chef in a restaurant, handling all sorts of meat but denying exposure to rabbits or rabbit meat.

Of the 8 patients infected by ticks, 5 lived on Cape Cod, 1 on Martha's Vineyard, and 2 in Plymouth County. Of the 2 probably infected by tick bites, 1 was located on Cape Cod and 1 in Waltham (metropolitan Boston). The case resulting from contact with an infested dog occurred on Cape Cod also. The 2 cases due to contact with rabbits occurred in Plymouth and Essex counties respectively.

### The Tick Problem

The south side of Cape Cod and the islands to the south—Martha's Vineyard, Nantucket and Naushon—are heavily infested. Ticks are less abundant on the north than on the south side of the Cape, and there are few to be found north of Plymouth, or inland beyond Middleboro and Taunton. Along the coast there is a marked diminution from Marion westward. *D. variabilis* (wood or dog tick), *H. leporis-palustris* (rabbit tick), and *Ixodes dentatus* are the most prevalent, however, *I. scapularis* (black-legged tick), *I. muris*, *I. marxi*, *I. cookei*, *I. brunneus* and *H. chordeilis* are also abundant.

The larvae and nymphs of *D. variabilis* engorge preferably on small rodents, which are the true breeding hosts of the immature instars. A few of these sometimes stray onto rabbits, larger mammals or birds, but it is questionable whether they are capable of moulting after engorging on these unusual hosts. The meadow mouse, *Microtus pennsylvanicus*, is the preferred host of larvae and nymphs in the Cape Cod area. Most adult forms attach to and engorge on large and medium-sized

mammals, the domestic dog being the favorite host. Man is readily attached to, but is only an accidental or stray host and not important to the survival of the species. In the Cape Cod area, adult ticks appear and are active from the latter part of April to the end of August.

The normal breeding hosts of adult and early stages of *H. leporis-palustris* are several species of hares and wild rabbits. Although this is the most important vector of tularemia in nature among rabbits and hares, it rarely bites human beings (as mentioned above), however, its larvae and nymphs are occasionally found on cats and dogs. Herman,<sup>22</sup> in 1938, found 18 out of 31 song sparrows infested with this tick on Cape Cod so that it can be distributed by the migration of birds.

*I. dentatus* appears to be a specific parasite of the *Lagomorpha* (rabbits and hares) at all stages,<sup>24</sup> but immature stages are sometimes found on rodents and birds. The normal hosts of the immature stages of *I. scapularis* are small mammals, particularly the white-footed mouse, but the adults attack a variety of large and medium-sized mammals straying occasionally onto man. *I. muris* appears to be at all stages a frequent parasite of small rodents, particularly the field mouse, occasionally, it attacks small migratory birds. *I. marxi* occurs normally on chipmunks and squirrels, and *I. cookei* infests medium-sized mammals, particularly *Garmipora*. *I. brunneus* and *H. chordeilis* are specific to birds. It is not yet known what part, if any, these ticks play in the transmission of tularemia.

It is readily conceivable how tularemia could be spread through the tick family and wild life once the infection has been introduced into a tick-infested area such as Cape Cod. *H. leporis-palustris* and *I. dentatus* could spread the disease from rabbit to rabbit, the former transmitting it to birds and the latter to field mice also. *I. brunneus* and *H. chordeilis* could spread it from bird to bird and *I. scapularis* and *I. muris* from mouse to mouse. In such a way a vicious circle could be formed, increasing the danger to man.

### The Rabbit Problem

Prior to 1937 no rabbits were imported privately from the West, however, 26,290 Western rabbits were liberated in Massachusetts in that year and up to and including 1940. Of these, 788 were released in the tick-infested counties of southeastern Massachusetts. The first case of tularemia appeared in Falmouth in June, 1937, whereas, the first shipment released in that area was in March, 1937. From then on, cases have appeared regularly in the area of high tick prevalence. It is interesting to note that all the cases occurring on Cape Cod have been on the south shore.

In March, 1941, a shipment of cottontail rabbits was released in the vicinity of Lawrence, Massachusetts, and in November of that year a case of

tularemia was reported from that area, resulting from the skinning of wild rabbits shot in hunting

In 1940, at the request of the Division of Fisheries and Game of the Massachusetts Department of Conservation, Belding and Merrill<sup>55</sup> examined post mortem 136 rabbits that had been imported by Massachusetts game clubs and had died in transit or shortly after their arrival in Massachusetts. Two of these rabbits were found to have tularemia. A previous series, in 1937, revealed no infection in 194 imported rabbits; therefore, the prevalence of tularemia in 2 out of 330 rabbits (0.6 per cent) was taken to correspond closely with the usually accepted incidence of 1 per cent infection among wild rabbits. The 2 tularemic rabbits were found in the shipments coming from Missouri and Arkansas (states with a total of 583 and 322 human cases reported for the period extending from 1937-1940).

The imported rabbits were admitted to Massachusetts under certification by accredited health authorities at the shipping points. The certificates stated that there had been no epidemic of tularemia or rabbit fever in the last two years in the counties in which the rabbits were trapped, and that these counties were free from contagious and infectious rabbit diseases. The presence of tularemia in certified rabbits from two states indicates that such guarantees are inadequate to prevent the inclusion of tularemic rabbits in these shipments.

Although there were no importations from 1942 to 1945, 4 cases of tularemia were reported during this period (2 from Cape Cod, 1 from Plymouth County, and 1 from Waltham). Three of these cases were ascribed to ticks, and 1 to contact with wild rabbits.

During 1946 approximately 3000 wild rabbits were again imported, mostly from Arkansas and Kansas, into Massachusetts by game clubs. Although none were released on Cape Cod, some were released in Bristol and Plymouth counties. During 1946 a case of tularemia was reported from Martha's Vineyard, and another from Boston. However, in 1947 there were 2 cases in Bourne (Cape Cod), and 2 in Plymouth County.

#### DISCUSSION

From the material presented above, it appears that tularemia did not exist in Massachusetts prior to 1937. Although the medical profession had known about the disease since 1911, no cases except the 3 contracted outside the Commonwealth were reported prior to that year. In the spring of 1937 the first importations of wild rabbits from the midwestern states began, and the first case of tularemia definitely contracted in Massachusetts was reported during the following summer from the tick-infested area of the Commonwealth.

The fact that these wild rabbits were imported from areas where tularemia was prevalent and that some were proved to be infected with tularemia, in

spite of certification from the exporting areas, leads one to believe that the disease was introduced into Massachusetts by this means.

Although these wild rabbits were released throughout the Commonwealth, only the tick-infested regions of Cape Cod and Plymouth County have persistently reported sporadic cases of tularemia because of the prevalence of ticks to maintain the focus. Fortunately, although ticks can spread and maintain a focus, there have been no outbreaks of any consequence in Massachusetts. This may be due to certain factors, as yet not fully known, limiting the spread of infection, even though the reservoirs and vectors are present in variable numbers. However, since there has been a regular occurrence of cases of tularemia in the tick-infested areas from 1937, one can assume that there is a small endemic focus in Massachusetts. The future of this focus cannot be predicted so far as its maintenance is concerned, however, its spread can be prevented by control of the tick population and by the placing of definite restrictions upon the introduction of fresh animal hosts and possible reservoirs such as wild rabbits.

The control of the tick population can be approached in several ways, none of which are very satisfactory in the ultimate eradication. Destruction with insecticides such as nicotine sulfate, sodium fluoride and DDT solutions is of value only on a very limited scale. Destruction of wild animal hosts as a means of eliminating the ticks from a given area seems an impossible task, for the arachnids are numerous and varied among both mammals and birds. The use of insect parasites such as the chalcid flies, if they became well established, could conceivably do much to reduce the tick population by killing a percentage of the nymphs. However, the two known chalcid parasites of ticks (*H. hookeri* and *I. caucurteri*) do not seem to be particularly attracted by *D. variabilis*, hence, their introduction is hardly an effective control measure for this tick.

Individual protective measures against ticks by man can be the most important factor in the avoidance of tularemic infections. Walking in woods and pastures should be avoided as much as possible during the tick season, if such walks are unavoidable, adequate clothing covering as much of the body as possible should be worn. Upon return from a heavily infested area, clothing should be removed and treated with some insecticide, and the body searched for any attached ticks. Particular care should be taken not to crush the ticks when removing them, since the infection can be acquired in this way. Ticks should also be removed from all household pets such as dogs before they are allowed to enter the house.

It has been shown that certification by authorities of exporting areas is inadequate in the prevention of the exportation of infected animals. Neither is the inspection of shipments at the point of release satis-

factory, for the disease is too easily overlooked in the gross Guinea-pig inoculations have been demonstrated to be the only sure method of diagnosis and identification, but this is expensive and impractical because it is applicable only to dead rabbits. Inasmuch as tularemia exists in practically all states exporting rabbits, the best safeguard against the introduction and spread of tularemia in Massachusetts seems to be the banning of the importation of cottontail rabbits from the West.

## SUMMARY

The history of tularemia is discussed, beginning with a description of a disease with a similar symptom complex by Homma in 1837 and including the monumental work by various men of the United States Public Health Service, who established the disease as a definite entity with specific causal relations.

The following modes of transmission are presented whereby man is infected by contact with infected wild animals, by ticks, by bloodsucking insects, by ingestion of contaminated food and water, and by inhalation.

The reported incidence of tularemia in Massachusetts consists of 14 cases occurring in ten years, with 78.7 per cent occurring in the southeastern sector (Cape Cod and Plymouth County area), 57.2 per cent were due to tick bites, 14.3 per cent were probably due to tick bites, 14.3 per cent were due to contact with infected rabbits, 7.1 per cent were due to contact with an infected dog and 7.1 per cent were due to contact with unknown sources.

Ticks capable of transmitting tularemia, particularly *Dermacentor variabilis*, *Haemaphysalis leporispalustris* and *Ixodes dentatus*, are most prevalent on the south side of Cape Cod and islands to the south, with diminishing numbers in Plymouth County and northward.

The appearance of tularemia in Massachusetts coincides with the beginning of importations of wild rabbits from midwestern states where tularemia is prevalent, and their release in the tick infested area of the Commonwealth. The existence of tularemia in these imported rabbits was proved in 1940 and a 1 per cent incidence was calculated.

Satisfactory means of controlling the tick population have not yet been devised. Personal prophylaxis against ticks is very important in the avoidance of infection.

Certification of imported wild rabbits is inadequate in the prevention of the introduction of tularemia into a previously tick-free state.

### CASE 34061

#### PRESENTATION OF CASE

A twenty-six-year-old married woman entered the hospital complaining of abdominal pain.

Two days before admission she began having generalized, crampy abdominal pain. She had a small bowel movement that day. On the following day she was unrelieved following a good bowel movement. She experienced some anorexia, but no nausea or vomiting. On the day of admission, the pain moved to the right lower quadrant and became steady. Examination of the blood by a physician showed a white-cell count of 12,000 and hospitalization was advised.

The patient was believed to be pregnant, her last period having occurred just two months previously. Her appetite had been "picky" for a month.

Examination showed tenderness and only slight spasm at McBurney's point, with cough and rebound tenderness. Rectal examination disclosed a tender

right vault, high up, and a normal left vault. The cervix was tender to motion. The uterus was enlarged and consistent with a two months' pregnancy.

The temperature was 98.6°F, the pulse 82, and the respirations 20. The blood pressure was 125 systolic, 70 diastolic.

Urinalysis was negative.

Immediately following admission, preoperative medication was given and operation performed.

#### DIFFERENTIAL DIAGNOSIS

DR GORDON SCANNELL. I assume that the enlarged uterus, in addition to the missed period, was the reason for thinking that this patient was pregnant—I should like to know if she had had children, because if she had been pregnant before and thought that she was pregnant, she was probably right. If she had not had children I should like to know how long she had been married.

DR MARSHALL K BARTLETT. This was her second pregnancy. She was seen by an obstetrician on the day of admission. He thought that she had a normal two months' pregnancy.

DR SCANNELL. In summary, this was a young married woman with a short history representing an acute surgical condition of the abdomen. We will therefore, on the date given, rule out chronic diseases and focus our attention on the immediate problem as it faced the surgeon on the night of admission. The symptoms were referable to the lower part of the abdomen and pelvis, there were definite signs of peritoneal irritation—namely, slight spasm at McBurney's point, and cough and rebound tenderness. Then too we have the signs of tenderness in the cul-de-sac and on motion of the cervix, which cannot be dismissed. If we are considering the pelvis and the acute problem, we think

of three systems the urinary tract, the gastrointestinal tract and the genital tract. I believe that we can rule out the urinary tract. This was not a good history for pyelitis, although we think of that in a person with an early pregnancy. The patient had no fever, the urine was normal, and there was no characteristic radiation of pain and no other data on which to justify that diagnosis.

When we come to the gastrointestinal tract we come to the obvious problem, which I am sure played a large role in the mind of the surgeon taking care of the patient. The thing to rule out — by operation, if necessary — is appendicitis. She did have a short history, with a shift of the pain from generalized abdominal to the right lower quadrant that is one of the cardinal symptoms of appendicitis. She had anorexia, which often occurs instead of nausea and vomiting, thus, one frequently sees acute appendicitis with the patient complaining of not having desire for food that day. On the other hand, nausea and vomiting are expected in an acute appendiceal disease, especially when one is thinking of the acute obstructive type, which is so dangerous. This patient had an elevated white-cell count and localized signs at McBurney's point. Against appendicitis, in addition to the absence of nausea and vomiting, is the absence of bowel symptoms. She had a normal bowel movement on the day before admission and a small one on the previous day that may have been normal. She did not give the history of mild constipation that so regularly goes with an acute appendicitis. The bowels move a little, but there is no satisfactory bowel movement. So much for appendicitis at the moment. Since we do not have to make the final decision, we can assume the academic point of view and say that she did not have enough to go with acute appendicitis. If appendicitis was present, it does not impress one as the acute obstructive type.

One might think of a Meckel's diverticulum, but I rule it out on the basis of the absence of obstructive symptoms and the presence of right-sided localization of the pain.

Gastroenteritis is a common catch-all diagnosis. This patient had neither gastric nor enteric symptoms.

Carcinoma even in this age group is important. We occasionally see carcinoma of the cecum or carcinoma of the appendix that may give this picture and lead to an operation for an acute condition. However, we have no data on which to base that diagnosis. There are other things that we might think of, such as diverticulitis of the cecum and a twisted epiploic appendix, both of which result in prominent bowel symptoms, of which this patient had no complaint.

Turning from the gastrointestinal tract to the pelvic organs, I think that we may find more fertile ground. I would rule out pelvic inflammatory

disease. She had no fever, was apparently not very sick and had no profuse menstrual irregularity of flow. She did not have the physical findings to go with it. A twisted cyst of some kind should be considered. The history is compatible with that diagnosis. She had vague, generalized abdominal pain shifting to one side and going low in the abdomen, with a slight suggestion of bowel symptoms but not very much. I assume that if she had a twisted cyst large enough to make her thus sick, the cyst would have been palpable. Furthermore, with a twisted cyst I would expect nausea and vomiting. In fact we have expected these symptoms right along but have not observed them.

The one diagnosis that we arrive at is the question of an ectopic pregnancy. Against that diagnosis there is only one real factor and not a really good argument against it. The patient had no bleeding, which is common in ectopic pregnancy. But there is no reason for bleeding irregularly at this point, unless there is rupture of the pregnancy, or leakage. In favor of extrauterine pregnancy are a good many things: the menstrual history and the skipped period, and something happening on one of the expected days of a period, which is not uncommon with ectopic pregnancy. She had the subjective symptoms of pregnancy, tenderness referred to the pelvis, and particularly tenderness on motion of the cervix. A pelvic appendix can also give tenderness on motion of the cervix but the factor *par excellence* that gives such tenderness is a little bleeding behind the uterus in the cul-de-sac or bleeding in one tube with tenderness high up on the right. Because it is high, there could well have been a small swelling in the right tube, which was tender, but could not be nicely delineated as an ovarian tumor.

The whole picture seems to be that of pelvic irritation. The very vague abdominal complaints without subsequent involvement of the gastrointestinal tract point to the uterus or ovaries. As the best possibility I would select ectopic pregnancy, which had just started to abort, causing leakage of blood into the cul-de-sac. The patient had not had a ruptured ectopic pregnancy in the dramatic sense.

A PHYSICIAN. I should like to say that I have seen a very similar picture in a patient who had a fibroma of the uterus that had degenerated.

DR. SCANNELL. I think that is a real possibility, especially with associated pregnancy, although I think that it might be picked up as an irregularity of the uterus on examination.

DR. BARTLETT. I saw this woman shortly after she was admitted and thought that she probably had acute appendicitis. The signs were rather well localized although we realized that they were not very striking. The tenderness was not of great magnitude and the spasm was minimal. We had

the benefit of feeling the uterus, which was large for an ectopic pregnancy and more like that of a normal pregnancy. I was somewhat comforted by the fact that the obstetrician, who was an experienced man, thought that it was a normal intra-uterine pregnancy. In any case we could not rule out appendicitis. We operated on her with that preoperative diagnosis.

#### CLINICAL DIAGNOSIS

Acute appendicitis

DR SCANNELL'S DIAGNOSIS

Ectopic pregnancy

#### ANATOMICAL DIAGNOSIS

*Twisted cyst of serosa of cecum*

#### PATHOLOGICAL DISCUSSION

DR BARTLETT When the peritoneum was opened there was a small amount of blood-tinged fluid in the peritoneal cavity. The appendix was normal. The terminal ileum was normal. There were abnormal lymph nodes in the mesentery. We could find no Meckel's diverticulum, and both tubes and ovaries were entirely normal. A low hanging cecum extended down over the pelvic brim and was delivered into the wound. Hanging from the posterior wall behind the base of the appendix was a pedunculated cyst the size of an English walnut. The stalk was about 3 cm long. The cyst was thin walled and had a 360° twist in its pedicle. The omentum was adherent to the surface of the cyst. Even then we did not know what it was. It was well on in the evening, but Dr Castleman was in the hospital and he came over and looked at it. The thing that occurred to me was the possibility of some queer second implantation of another ovum, but it did not seem to be that, and Dr Castleman agreed. The cyst was removed very easily, and the patient made an uneventful recovery.

DR BENJAMIN CASTLEMAN In gross the specimen looked like a paraovarian cyst that had twisted and at the site of the twist was a small hematoma, which resulted from the twist. The wall was thin and contained straw-colored fluid with a bit of hemorrhage in it as a result of the twist. On microscopic examination no definite diagnosis could be made except that of cyst. It probably was congenital in origin. It is conceivable that it might have been an appendix epiploica that had slowly twisted, with resultant central necrosis and cystification. The few twisted appendices epiploicae that I have seen have all been on the left side in the sigmoid, where there are more fat tabs. These, then, are the two possibilities: a congenital rest or a twisted appendix epiploica that had degenerated.

DR BARTLETT I have never seen anything like this. I would be interested to know if anyone has

seen a cyst of this type arising from the cecum or anywhere in the gastrointestinal tract.

DR FALLS B. HERSHEY Do not ovarian cysts occasionally move from their attachment to the ovary?

DR CASTLEMAN It would not have been implanted on the posterior wall of the cecum.

DR HERSHEY Does a reduplication from that area ever give this picture?

DR CASTLEMAN I have never seen one as small as this. It was 2 or 3 cm in diameter.

DR RICHARD H. SWEET I have seen cysts arising from embryonic rests in connection with the ovary. I recall a case in this hospital, in which operation was performed by Dr George A. Leland. It was a sizable cyst, however, ovarian in origin.

DR CASTLEMAN There is no evidence for that here.

### CASE 34062

#### PRESENTATION OF CASE

A sixteen-year-old high-school boy entered the hospital complaining of fever, sweats, aches and pains.

He had been in excellent health all his life until three months before admission, when he first noticed a dull aching pain in the legs and pelvic bones. The pain was mild at first, being present only on walking, and after a week was replaced by a vaguely localized but persistent aching of the right leg, mainly in the muscles rather than in the joints, that was worse at night and not particularly aggravated by motion. The pain was often severe enough to prevent sleeping and, in spite of heat treatments, grew gradually worse. X-ray studies of the spine at that time were negative. The patient was not acutely ill until three weeks before entry, when he was awakened by a severe aching pain across the lower back and was found trembling and perspiring profusely. The following morning the temperature was 100°F. Within two or three days the backache subsided, but he began to notice pleuritic pain in the left anterior portion of the chest and later on the right side as well. He was given sulfonamide tablets for a week but continued to have an irregular fever, the temperature ranging up to 102°F, profuse sweating and generalized muscle aches as well as pleuritic pain. An x-ray film of the chest taken one and a half weeks after the onset of these symptoms was said to show "virus pneumonia." After two weeks the temperature came down somewhat. The patient was then given penicillin in wax on two consecutive days. After each injection the temperature rose higher, and he felt worse. On the day before entry the temperature reached 103°F. There had been no coryza, cough or gastrointestinal symptoms except for anorexia.

Physical examination showed a well nourished boy, who was rather well developed for his age. He seemed inattentive, restless and irritable, but not in distress. The gums were slightly reddened and tender, and the throat was moderately injected. Considerable tenderness was elicited just anterior to the sternomastoid muscles on both sides of the neck. This tenderness seemed to be over several pea-sized, deep lymph nodes. No other adenopathy was noted. The heart was of normal size, with a generalized soft, blowing systolic murmur. The abdomen was normal, the liver and spleen were not palpable.

The temperature was 101.6°F, the pulse 110, and the respirations 20. The blood pressure was 130 systolic, 80 diastolic.

Urinalysis showed a specific gravity of 1.010, a + test for albumin and a 0 test for sugar. The hemoglobin was 10.5 gm, and the white-cell count 3200. The differential count revealed 89 per cent small lymphocytes and 11 per cent "atypical lymphocytes" and no polymorphonuclear leukocytes. The platelets were normal. Widal, Brucella, tularemia and heterophil-antibody agglutinations were negative. An x-ray film of the chest was clear.

In the hospital the patient continued to run a low-grade fever, his condition growing slowly but progressively worse. After two and a half weeks the blood smear showed numerous large cells that were thought to be monoblasts or stem cells. The white-cell count, after an initial drop to 1400, rose steadily to as high as 40,500 after a few weeks. Differential counts continued to show a virtual absence of polymorphonuclears and numerous atypical monocytes and "blast" forms each averaging about 40 per cent of the total. Additional x-ray films of the chest revealed small areas of increased density scattered throughout the lower lobes. This process on repeated x-ray examination seemed to become more marked, and the areas of density somewhat confluent. X-ray studies of the cervical spine and ribs disclosed no definite evidence of bone destruction. During the fourth hospital week x-ray examination of the skull showed a soft-tissue mass in the right frontal area just anterior to the coronal suture. There appeared to be destruction of the outer table underlying it. The patient was given several blood transfusions but failed steadily, and expired approximately five and a half weeks after admission.

#### DIFFERENTIAL DIAGNOSIS

DR. BERNARD M. JACOBSON This case is obviously one of acute leukemia. The initial symptoms in this patient are extremely common in most cases of acute leukemia—namely, those suggestive of infection and bone and joint disease. During the three months before the patient entered the hospital the differential diagnosis could have been extended to a large number of different conditions, including virus infection, rheumatic fever, brucellosis, ery-

thema nodosum, periarteritis nodosa and lupus erythematosus. During the three weeks before entry the patient undoubtedly had pleural or pulmonary infection with regression, as noted by the first normal chest film after entry. We are not told anything regarding the blood picture during these three months, but it is easily imaginable that the blood morphology was nondiagnostic.

After entry the first physical signs that can be related to the later established diagnosis are redness and tenderness of the gums and cervical lymphadenopathy. The soft, blowing systolic murmur does not indicate organic heart disease but is more likely to be due either to the fever or to the anemia. The clinical course included fever and the development of increased areas of infiltrates in both lungs. The last chest film that I viewed appeared to show dilatation of the heart, diffuse pulmonary infiltration and pleural effusion, more marked on the right side. The presence of only minimal lymphadenopathy and the absence of splenomegaly are quite common in acute leukemia.

The initial blood examination revealed an anemia and a leukopenia. Although we are not informed of the course of the hemoglobin this level must have fallen significantly during the remainder of the hospital stay. In most of the smears the red cells were generally slightly macrocytic, with only slight variation in size and shape, and were well filled with hemoglobin. The platelets appeared normal or slightly reduced. The appearance of the red cells is certainly compatible with a myelophthisic anemia.

The most striking laboratory finding is the white-cell picture. I had the opportunity to study six blood smears. The initial smear revealed a majority of the white cells to consist of apparently mature small lymphocytes, but within four days the picture had changed. The remaining smears showed successively large numbers of cells, which varied in size from that of a normal monocyte to two or three times as large as a normal monocyte. Many of the cells showed serrated margins suggestive of pseudopodia. The cytoplasm ranged from lightly basophilic to intensely basophilic, often vacuolated and with or without a moderate number of azurophilic granules. The nuclei of these cells were either round or oval or reniform or even lobulated, with a skin-like coarse chromatin and containing one or more nucleoli. The most mature of these cells appeared to be intermediate between the mature monocytes and the obvious blast forms and can be termed promonocytes. The blast forms with extremely large and serrated margins looked unlike myeloblasts or lymphoblasts and can be called monoblasts. The changes in the white-cell picture during the course of the disease are not uncommon in monocytic leukemia and have recently been well described.\*

\*Rappaport, A. E. and Kurel, V. H. Monocytic leukemia. *Blood* 2:333-355, 1947.

Three clinical features of this disease can be readily explained by the diagnosis of monocytic leukemia. The initial bone and joint symptoms were possibly due to leukemic infiltrations of the periosteum or juxta-articular bone of the lumbar spine, pelvis and femurs. The later pulmonary findings are more likely to have been due to leukemic infiltrates rather than to infection. Finally, the soft-tissue mass noted in the right frontal area of the skull was probably also due to a leukemic tumor. Whether this tumor had the appearance of a chloroma or not I cannot predict.

During the early part of the hospital stay the abnormalities of the white cells could have reasonably brought up the question of leukemoid monocytic reaction in various diseases such as tuberculosis, lymphoma, lupus erythematosus and subacute bacterial endocarditis, as well as the monocytic phase sometimes seen in agranulocytosis. The later appearance of numerous blast forms, however, rendered these possibilities extremely unlikely.

In view of the complete absence of myeloblasts and myelocytes in the blood smears I believe that we can dismiss the possibility of the Naegeli type of monocytic leukemia — that is, a variant of myelogenous leukemia.

My diagnosis is acute monocytic leukemia.

DR LOWREY F DAVENPORT: It might be well to emphasize the earlier weeks of this patient's illness before abnormal cells appeared in the blood stream. We were confronted with a fever of unknown origin, enlarged cervical lymph nodes and a complete absence of granulocytes. For a time we hoped that the condition was an agranulocytosis following sulfadiazine, which had been given elsewhere. The enlarged cervical lymph nodes and a progressive increase in the mononuclear cells temporarily raised the hope of infectious mononucleosis. In fact we built a very strong circumstantial case on this premise. This boy's roommate had had, two weeks prior to the patient's initial symptoms, an episode of fever with enlarged lymph nodes that could have been infectious mononucleosis. Unfortunately, no blood studies were made. For several weeks, then, we proceeded on the assumption that this more hopeful diagnosis was possible. It was not until the appearance of large numbers of abnormal cells in the peripheral blood that the possibility of an infectious mononucleosis masked by agranulocytosis was dismissed.

#### CLINICAL DIAGNOSIS

Acute monocytic leukemia

#### DR JACOBSON'S DIAGNOSIS

Acute monocytic leukemia.

#### ANATOMICAL DIAGNOSES

*Lymphatic leukemia*

*Leukemic infiltration of bone marrow, spleen, lymph nodes, liver, kidneys, lungs, testicles, pericardium, pleura and voluntary muscle*

Hydrothorax, bilateral, slight

Ulcers, nonspecific, of esophagus, stomach and small intestine

#### PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY: This case, as Dr Davenport pointed out, was very confusing until the blood picture in the last few weeks of life became frankly leukemic. A large proportion of the cells were extremely immature, but the hospital hematologists who saw the smears agreed with Dr Jacobson that the cells were probably monoblasts. I could reach no other conclusion myself when I reviewed the blood smears. The autopsy findings, however, were inconsistent with a diagnosis of monocytic leukemia, and I am at a loss to explain the discrepancy.

Widespread leukemic infiltration was present in the bone marrow, lymph nodes, spleen, thymus, liver, kidneys, testicles and lungs, as well as many tumor-like masses in skeletal muscles and serosal tissues. None of these tumors had the greenish color of chloromas. The pulmonary infiltration was particularly extensive. It was almost exclusively interstitial but so extensive that the intervening alveoli were completely collapsed and the tissue seemed solidly consolidated.

The problem of the case lies in the nature of the cells composing the infiltrate. They were similar in all areas and appeared in the fixed tissue sections to be characteristic, quite mature lymphocytes. The cells were small, the cytoplasm scanty and basophilic, and the nuclei predominantly round with peripheral chromatin and few conspicuous nucleoli. No cells of the large, very immature type, so numerous in the peripheral blood, were to be found, and very few cells that suggested monocytes in any stage of development were present. I am forced on the basis of the anatomic material to make a diagnosis of lymphatic leukemia, and you will have to choose for yourselves whether to trust the clinical or the anatomic evidence.

## STREPTOMYCIN FOR URINARY-TRACT INFECTIONS

THERE are now several recognized methods that have been employed with varying success in the treatment of urinary-tract infections. Methenamine with acid phosphate is somewhat effective as a urinary antiseptic. Acidification of the urine with mandelic acid or one of its salts has proved useful in many cases. The sulfonamides, however, have proved much more successful in the simple acute infections. Since gram-positive organisms that are susceptible to penicillin are infrequent as causes of infection of the urinary tract, that antibiotic has only limited uses in this field. On the other hand, streptomycin should prove more useful in the therapy of these infections since it is the most

effective agent now available against the gram-negative bacilli that are the predominant bacterial agents in infections of the urinary tract.

The results of streptomycin treatment of urinary-tract infections have not proved universally favorable. In 409 cases collected by the Committee on Chemotherapeutics and Other Agents of the National Research Council,<sup>1</sup> the over-all recovery rate was only 42 per cent. Similar results were obtained in many clinics. Perhaps the most important causes of such failures reside in the nature of the infections that are treated. That is particularly true of chronic cases of pyelonephritis in which there are underlying anatomic defects that interfere with proper drainage, as well as destructive processes that are difficult to heal and remain the source of persistent infection or sites for reinfection. It is just these conditions that also interfere with the success of other forms of therapy that have usually been used without benefit in these cases before streptomycin was tried.

One of the most important causes of streptomycin failures, however, is the rapid replacement of streptomycin-sensitive organisms in the urine by organisms that are highly resistant to streptomycin. In many cases the resistant bacteria have increased more than eight-thousandfold in a matter of a few hours after the first dose of streptomycin was given.<sup>2</sup>

Since the development of resistant bacteria in vitro is usually accomplished by exposing organisms to subeffective concentrations of the antibacterial agent, it is supposed that the use of massive doses of streptomycin would prevent the development of resistant bacteria in the urine. Unfortunately, the range of streptomycin dosage that is feasible in human beings is very narrow, and the upper limit of such doses is not much greater than the amounts that are therapeutically effective. The use of maximum doses, therefore, has not proved successful in preventing the appearance of resistant strains that interfere with the efficacy of therapy.<sup>3</sup>

Alkalinization of the urine, however, has proved extremely useful in this respect. It has been shown that within the range of reaction attainable in the urine—namely, between pH 5.5 and 8.0—the antibacterial effect of any given concentrations of streptomycin may be increased up to eightyfold.<sup>4</sup> A

The Dispensary Food Clinic, at the time of its establishment, was a unique experiment of its kind and has been the model for over fifty similar clinics that have been set up throughout the world. Here patients have learned the bearing of diet on their individual health problems, with consideration given to their religious and racial backgrounds and their economic situations.

## MASSACHUSETTS MEDICAL SOCIETY

### DEATHS

**MANSFIELD**—James A. Mansfield M.D., of Boston died on June 29. He was in his eighty-first year.

Dr. Mansfield received his degree from Jefferson Medical College of Philadelphia in 1896.  
A son survives.

**POLIAK**—Mendel Poliak M.D. of Springfield died on September 15. He was in his sixty-first year.

Dr. Poliak received his degree from Université de Montpellier Faculté de Médecine in 1922. He was a member of the staff of Wesson Memorial Hospital.

**RICKER**—Carroll H. Ricker M.D. of Worcester, died on September 6. He was in his eightieth year.

Dr. Ricker received his degree from Tufts College Medical School in 1907. He was a member of the staff of Worcester City Hospital and was a fellow of the American Medical Association.

His widow and a daughter survive.

## MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

### TRICHINOSIS IN MASSACHUSETTS

The problem of trichinosis is much larger than is generally realized. In the ten-year period 1936-1945, a total of 287 cases were reported to the Massachusetts Department of Public Health with 7 deaths. Cases have been reported with regularity from all areas, a total of eighty-one different communities reporting one or more cases during the ten-year period. However, there can be little doubt that many times as many persons were so mildly ill of trichinosis as never to have come under medical care.

Surveys of autopsy material in various localities throughout the United States have shown an incidence of trichinosis infections varying from 16 to 36 per cent. It is generally recognized that man becomes infected by eating trichinosis pork, which in turn comes from hogs fed on garbage containing scraps of uncooked trichinosis pork. The average incidence of trichinosis among hogs in the United States during the past fifty years has remained practically unchanged at a level of approximately 1.5 per cent. It has been estimated that 96,849,000 hogs were slaughtered in the United States during 1944, and the total production of pork was 12,893,000,000 pounds.

This amount of pork would furnish about 30,000,000 individual servings, or approximately 200 servings per person in the United States, of which 3 would contain trichinae. Since the average length of life of Americans is now over sixty-four years and an average of 200 servings of pork are annually eaten per person, for the lifetime of each person nearly 200 meals of pork containing trichinae are consumed.

Another way of visualizing the magnitude of the problem in Massachusetts is to estimate the number of persons acquiring the parasites. Each year about 70,000 persons are added to the population by births. Even at the lowest estimate 16 per cent of this number, or 11,200, should show symptoms each year instead of the average of less than 30 cases actually reported annually during the last ten years.

The onset of the illness is of variable intensity, depending upon the amount of infected meat eaten and the abundance of trichinae in the meat. The first symptoms are generally gastrointestinal, consisting of nausea, vomiting, abdominal pain and diarrhea lasting for three to five days. These are followed by a period of muscular aching, pain and tenderness, chills, a temperature not unlike that in typhoid fever, cough, edema of the eyelids and skin rash. Not infrequently, signs and symptoms of pulmonary, cardiac and central-nervous system involvement are found. This period of peripheral symptomatology lasts as long as the adult worm is producing larvae—five to seven weeks. Death occurs most frequently from the third to the sixth week. Although recovery is usually complete, vague rheumatic pains may persist for about a year.

The most frequent laboratory aid is the elevated eosinophil count. The precipitin test is highly sensitive but is negative early in the illness, three to four weeks often being required before it is elevated. The skin test is of value if there is first an initial negative response followed by a positive reaction at a later date. Muscle biopsy, if positive, makes the diagnosis certain.

Various measures have been advocated in the control of trichinosis, including destruction of rats, elimination of garbage and offal from the feed of hogs, cooking of garbage to be fed to hogs, proper processing of pork products customarily eaten without cooking, microscopical inspection of pork and education of the public in the necessity of adequately cooking pork and pork products.

Processing of pork and its products means the treatment by freezing, cooking, smoking, curing or other methods that will render nonviable any trichinae present in the meat. Cooking and freezing are the easiest and most readily accessible methods. Trichinae are killed at a temperature of 55°C (131°F). Federal regulations require that, in the killing of trichinae by heat, all parts of the meat be raised to a temperature of 58.3°C. (137°F), the American Public Health Association recommends

that all fresh pork and its products be cooked at a temperature and for a time sufficient to allow all parts of the meat to reach a temperature of at least 65°C (150°F)

Trichinous meat in sections of 15 cm or less can be rendered noninfectious by refrigeration at a temperature of 5°F (−15°C) for twenty days, −10°F (−23°C) for ten days or −20°F (−30°C) for six days. It has also been found that raw pork in commercial quantities may be rendered free of infective trichinae by reduction of its temperature to −35°C (−31°F) for a short time or by freezing at −17.8°C (0°F) for seventy-two hours. In ground meat, encysted trichinae are killed in a few minutes at a temperature of −17.8°C (0°F). In most deep-freezing cabinets, such as those used in the home, temperatures varying from 0 to 5°F are usually maintained, and thus another method of assuring trichina-free meat has become available to the individual consumer.

Recently the President's committee for the conservation of food recommended that meat should not be overcooked. However, it is important that the consumer should not go to the other extreme of undercooking meat, particularly pork and its products, unless he is unreservedly certain that it has been properly processed beforehand.

\*Three-year median

†Five-year median

##### COMMENT

Diseases above the seven-year median are chicken pox, diphtheria, dog bite, bacillary dysentery, mumps and salmonellosis.

Diseases below the seven-year median are lobar pneumonia, measles, meningococcal meningitis, poliomyelitis and scarlet fever.

Chicken pox showed a marked increase in December, bringing the year's total to the second highest since 1916. Mumps reached the highest peak of the year in December,

which probably indicates that 1948 will be a mumps year. The seasonal increase in diphtheria continues, returning to the level of the late spring of 1947.

Only one case of meningococcal meningitis was reported after seven years of high prevalence in which 60 cases were once reported in December.

Scarlet fever dropped to the second lowest level ever reported, the total for 1947 being the lowest since 1905. Although the incidence of measles is low, the usual seasonal increase has brought the total to three times the number of cases reported for November.

##### GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anthrax was reported from Franklin, 1, total, 1.  
 Diphtheria was reported from Bedford, 1, Boston, 9, Brookline, 5, Chelsea, 2, Chicopee, 1, Everett, 1, Holyoke, 2, Malden, 2, Revere, 8, Somerville, 6, total, 37.  
 Dysentery, bacillary, was reported from Clinton, 1, Greenfield, 1, Salem, 1, Swampscott, 3, Worcester, 13, total, 19.  
 Malaria was reported from Boston, 1, Lawrence, 1, Marion, 1, Medford, 2, Northampton, 1, Uxbridge, 1, total, 7.  
 Meningitis, meningococcal, was reported from Worcester, 1, total, 1.  
 Meningitis, Pfeiffer-bacillus, was reported from East Longmeadow, 1, Everett, 1, Lawrence, 2, Quincy, 2, West Springfield, 1, Worcester, 1, total, 8.  
 Meningitis, pneumococcal, was reported from Cambridge, 1, Holliston, 1, Pittsfield, 1, total, 3.  
 Meningitis, undetermined, was reported from Boston, 1, Pittsfield, 1, Somerville, 1, Springfield, 1, Worcester, 1, total, 5.  
 Poliomyelitis was reported from Cambridge, 1, Framingham, 1, Northampton, 1, Rockland, 1, Sherborn, 1, Southboro, 1, Worcester, 1, total, 7.  
 Salmonellosis was reported from Belmont, 1, Cambridge, 4, Montague, 1, New Bedford, 1, Revere, 1, Swampscott, 1, total, 9.  
 Septic sore throat was reported from Boston, 1, Merrimack, 3, Milton, 1, total, 5.  
 Trachoma was reported from Worcester, 1, total, 1.  
 Trichinosis was reported from Cambridge, 2, Pittsfield, 1, Salem, 1, Stoneham, 1, total, 5.  
 Typhoid fever was reported from Boston, 1, Fall River, 2, Newton, 1, total, 4.  
 Undulant fever was reported from Attleboro, 1, Boston, 1, Danvers, 1, Rutland, 1, total, 4.

#### MISCELLANY

##### SCHOLARSHIPS FOR NURSES

The Greater Boston Nursing Council recently announced that scholarships and loan funds for students are available at the nurses' training schools of the following institutions: Beth Israel Hospital, Mt. Auburn Hospital, Children's Hospital, Faulkner Hospital, Massachusetts General Hospital, Massachusetts Memorial Hospitals, New England Deaconess Hospital, Newton-Wellesley Hospital, Peter Bent Brigham Hospital, Simmons College, Boston College, Melrose Hospital, and New England Hospital for Women and Children.

##### NOTE

The following appointments to the teaching staff of Harvard Medical School were recently announced: Frederick Chapman Robbins, of Bronxville, New York (A.B. University of Missouri 1936, M.D. Harvard University 1940), assistant in pediatrics; Henry Mitchell Putnam of Westwood (Ph.B. Yale University, M.D. Harvard University 1935), assistant in pediatrics; Walter Higbee Caskey, of Cambridge (M.D. Harvard University 1946), research fellow in comparative pathology and tropical medicine; Victor Clarence Vaughn, III, of Richmond, Virginia (A.B. Harvard University 1939, M.D. Harvard University 1943), research fellow in pediatrics; Samuel Waldfogel, of Detroit, Michigan (S.B. Wayne University 1938, M.A. University of Michigan 1939, Ph.D. University of Michigan 1946), research associate in psychiatry; Ronald Charles Sniffen, of Milton (M.D. University of Toronto 1936), instructor in pathology; Edgar Breck Taft, of Cambridge (M.D. Yale University School of Medicine 1942), instructor in pathology; Dante Francesco Campagna-

Pinto of Cambridge (A B Harvard University 1939, M D Harvard University 1943) assistant in pathology John Merrill Craig of Berkeley, California (A B University of California, 1936 M A University of California 1938 M D Harvard University 1941) assistant in pathology Melvyn Bertram Black, of Boston (A B Harvard University 1940 M D Harvard University 1943) research fellow in pathology Gilcin Finley Meadors, Jr of Washington D C (S R Mississippi College 1936 M D Tulane University of Louisiana 1940 M P H Johns Hopkins School of Public Health and Hygiene 1947) instructor in preventive medicine John Platt Hubbell Jr of Brooklyn (A B Williams College 1940 M D Harvard University 1943) assistant in pediatrics Donald Emerson McLean of Winchester (A B Harvard University 1938 M D Harvard University 1943) assistant in pediatrics Harold Edelhoch of Bronx New York (A B New York University 1943 A M Princeton University 1946, Ph D Princeton University 1947) research fellow in physical chemistry Drummond Ellis of Glasgow Scotland (B Sc Glasgow University 1944) research fellow in physical chemistry James Alexander Wolff of Boston (A B Harvard University 1935, M D New York University College of Medicine 1940), research fellow in pediatrics Arthur Francis Battista of Ontario Canada (B Sc McGill University 1943 M D C M McGill University 1944 M Sc University of Western Ontario 1947) research fellow in physiology Harold Scarborough of West Yorkshire, England (M B Ch B University of Edinburgh Scotland 1932 Ph D University of Edinburgh Scotland 1938) research fellow in physiology Melvin Hyman Kaplow, of Cambridge (A B Harvard University 1942) Harold C Ernst, fellow in bacteriology and immunology, Doreen Nightingale, of Loodoo England (M R C S, L R C P University College Hospital Medical School 1939 M B B S Looch University College Hospital Medical School 1940, M S Lond and F R C S England 1945), research fellow in surgery John Butler Tomkins of Waverley (S B Wesleyan University 1926 M D Tufts College Medical School 1935) instructor in psychiatry and Jacques Lewin of Paris France (M D Faculté de Médecine Paris 1929 Licence en Sciences Faculté des Sciences Paris 1933 M D (Diplôme d'Etat) Faculté de Médecine Paris 1947) research fellow in physical chemistry

### NATIONAL INSTITUTE OF HEALTH

Establishment of an experimental-biology and medicine institute, in the National Institute of Health of the United States Public Health Service has been announced. The new research institute will combine the functions of the Division of Physiology and the Pathology and Chemistry Laboratories and will permit greater co-ordination of scientific investigations.

Dr William Henry Schrell Jr, chief of the Division of Physiology, has been named director of the new institute and he will also serve as associate director of the National Institute of Health.

Formation of the Institute is part of a wider organization of the National Institute of Health, according to Dr Thomas Parran, surgeon general of the Public Health Service. Four other divisions and laboratories engaged in scientific research will also be consolidated into two additional institutes all of which will be modeled after the National Cancer Institute.

### BAY STATE SOCIETY FOR CRIPPLED AND HANDICAPPED

The Bay State Society for the Crippled and Handicapped has made a grant of \$12,000 for the work of the Sezure Unit of the Neurological Institute at the Children's Medical Center in Boston.

### HOSPITAL SURVEY AND CONSTRUCTION ACT

As of January 9, according to the Washington Report on the Medical Sciences 92 applications for construction of hospitals, dispensaries and health centers under the Hill-Burton Hospital Survey and Construction Act has been approved. The estimated outlay will be \$40,765,702 of which the Federal Government will provide \$13,381,548. The states so far included in the list are Alabama, Florida, Illinois, Indiana, Kentucky, Mississippi, New Mexico, North Carolina, Oklahoma and Texas.

## CORRESPONDENCE

### SHORTAGE OF NURSES

To the Editor: I read with interest the editorial "Shortage of Nurses," which appeared in the January 1 issue of the *Journal*.

You may know that House Bill 90 which has been filed with the 1948 General Court of Massachusetts, if enacted, would permit registration by women at the age of twenty rather than twenty-one a point discussed in the editorial.

In the light of information obtained by our Personnel Policies and Practices Committee we question the statement that the average nurse in Massachusetts works only a forty-four hour week. There is a trend in that direction but statistics show forty-eight hours to be the average work week in this area.

We thank you for the editorial and the points made in it especially your plea to exert every effort to obtain for nurses their proper recognition and economic stability.

HELENE G LEE, Executive Secretary  
Massachusetts State Nurses Association

420 Boylston Street  
Boston

### FURTHER NOTES ON FOLIC ACID

To the Editor: It has been a great help to me to have been able to follow, through the many articles published in the 1947 issues of the *Journal* the conflicting studies on the use of folic acid in the deficiency syndromes associated with macrocytosis of the red cells. I am referring to particular to the two progress reports "Hematology," by Dr William Dameshek to the September 18 and 25 issues and the more recent ones on "Pteroylglutamic Acid and Related Substances," by Dr Frederick Sargent, II, in the October 30 and November 6 issues.

The consensus seems to be that folic acid and related substances help in the control of the two manifestations of deficiency syndromes associated with macrocytosis of the red cells—namely changes in the gastrointestinal tract and changes to the blood and blood forming organs—but that folic acid has no influence on the third manifestation—changes in the central nervous system which is the most serious with the resulting subacute combined degeneration of the spinal cord.

Words of warning on the use of folic acid even for the control of the first two manifestations of the deficiency syndrome have been sounded. I refer in particular to the opinion of Dr Russell L Hadeo of the Cleveland Clinic who wrote, in an article entitled "Treatment of Pernicious Anemia" (*Postgraduate Medicine* 1:131-135, 1947) that he was relying on liver extract for the present, because folic acid in his opinion had as yet an undetermined place in treatment. More recently, in the Boston issue (September 1947, number) of the *Medical Clinics of North America* Drs Helen V Belding and Joseph F Ross in an article entitled "Recent Advances in Hematology," have stressed the very definite therapeutic limitations of folic acid in the deficiency syndrome associated with macrocytosis. The fact that folic acid is an effective hematopoietic agent in the anemia characterized by macrocytosis and a megaloblastic bone marrow is not denied but the authors stress what is the most important point in my opinion, that folic acid not only has little influence in altering the changes in the central nervous system but also is unable to prevent them from developing even though the hematologic status remains normal. More recently another warning of disastrous consequences has been given against the use of folic acid even in the control of the changes in the gastrointestinal tract and in the blood and blood forming organs, in spite of the many articles in the recent literature regarding its efficacy in the control of these two manifestations of the deficiency syndrome associated with macrocytosis. Dr O C Hansen Pruss in an article entitled "Relapse of Patients with Pernicious Anemia Receiving Folic Acid" (*American Journal of the Medical Sciences* 214:465-468, 1947) reports 2 patients who were suffering from pernicious anemia and relapsed while receiving folic acid; these patients responded well to liver extract.

It seems to me as a practicing physician that in answer to the patient with the deficiency syndrome associated with macrocytosis who demands the use of the new drug

appeared on the medical horizon, I should reply after analyzing the data submitted to you that by using folic acid he would in the light of present knowledge be taking considerable risk and be spending considerable money, whereas by taking liver extract he would be obtaining sure and proved control and at the same time be saving considerable money

## BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

*Methods of Vitamin Assay* Prepared and edited by The Association of Vitamin Chemists, Incorporated. 8°, cloth, 189 pp. New York: Interscience Publishers, Incorporated, 1947. \$3.50.

This standard manual was compiled by a committee of scientists recognized as authorities in vitamin research, with the assistance of a large staff of competent reviewers who were not members of the Association. The scope of the book is limited, since only such methods are included as have been successfully used by several committee members, thus representing the combined knowledge and experience of many persons. Special chapters are devoted to each of the important vitamins, and each chapter concludes with a selected list of references to the vitamin under discussion. The manual is recommended as a reference source for all medical and laboratory libraries.

*The American Illustrated Medical Dictionary* A complete dictionary of the terms used in medicine, surgery, dentistry, pharmacy, chemistry, nursing, veterinary science, biology, medical biography, etc., with their pronunciation, derivation, and definition. By W. A. Newman Dorland, A. M., M. D. Twenty-first edition. 8°, cloth, 1660 pp., with 880 illustrations. With the collaboration of E. C. L. Miller, M. D. Philadelphia: W. B. Saunders Company, 1947. \$8.50.

This standard, authoritative dictionary, last published in 1944, has been revised to include the voluminous medical terminology resulting from the research of the war years. In addition to the actual war medicine and surgery, new words have been added in the fields of tropical medicine, aviation medicine, medical zoology and mycology, biochemistry and pharmacology, including antibiotics, enzymes, vitamins and endocrines, and physics and nucleonics, including the application of radioactive isotopes. The names of proprietary medicines have been reviewed, and obsolete terms have been eliminated from the present edition. The book is well published in every way and should be in all medical and public libraries and institutions and also is recommended to all physicians and persons needing an up-to-date medical dictionary.

## NOTICES

### ANNOUNCEMENTS

Dr. Thomas J. Anglen and Dr. Knowles B. Lawrence announce the association with them of Dr. Martin L. Bradford in the practice of general surgery at 1180 Beacon Street, Brookline.

Dr. Bernard Bloom announces the opening of his office for the practice of urology at 67 Chestnut Street, Springfield.

Dr. Kurt H. Thoma announces the association of Dr. Daniel J. Holland, Jr., in the practice of oral surgery, and the removal of their offices to 1180 Beacon Street, Brookline.

Dr. Robert S. Thomson announces the removal of his office for the practice of general surgery to 866 Main Street, Fitchburg.

## MASSACHUSETTS MEDICO-LEGAL SOCIETY

The winter meeting of the Massachusetts Medico-Legal Society will be held in the George Burgess Magrath Library, Department of Legal Medicine, Harvard Medical School, on Wednesday, February 11, at 2:30 p.m.

### PROGRAM

Business Meeting

Beryllium Pneumoconiosis Walter W. Jetter, M.D.

Blood Concentrations of Barbiturates in Relation to Toxic Effects R. S. Fisher, M.D., and J. T. Walker, Ph.D.

Collation

## FELLOWSHIPS IN PUBLIC HEALTH

Fellowships leading to a master's degree in public health in the field of health education are again being offered to any qualified United States citizen between the ages of twenty-two and forty.

Candidates must hold a bachelor's degree from a recognized college or university at the time the application is filed, and must be able to meet the entrance requirements of the accredited school of public health of their choice. Proof of acceptance at such a school must be furnished before applications are submitted to the Fellowship Awards Committee for consideration. In addition to the bachelor's degree, courses in the biologic sciences, sociology and education are required. Training in public speaking, journalism and psychology and work in public health or a related field are considered desirable.

The fellowship consists of eight or nine months of academic work, which begins with the fall term in 1948, and three months of supervised field experience in community health-education activities in a local health department. The academic training includes courses in public-health administration, epidemiology, public-health and school education, problems in health education, community organization, information techniques and others.

Information and application blanks may be obtained from the National Foundation for Infantile Paralysis, 120 Broadway, New York 5, New York.

## AMERICAN ASSOCIATION OF PATHOLOGISTS AND BACTERIOLOGISTS

The annual meeting of the American Association of Pathologists and Bacteriologists will be held at the Jefferson Medical College, Philadelphia, on Friday and Saturday, March 12 and 13. Half a day will be devoted to a consideration of "Diseases of Bones." Contributions to this symposium are invited, but all material should reach the Secretary not later than Saturday, February 14. All papers, including illustrative material, must be presented within a limit of ten minutes.

Further information may be obtained from the Secretary, American Association of Pathologists and Bacteriologists, 2085 Adelbert Road, Cleveland 6, Ohio.

## SOCIETY MEETINGS AND CONFERENCES

### CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, FEBRUARY 12

#### FRIDAY, FEBRUARY 13

\*9:00-10:00 a.m. Recent Advances in Our Knowledge of Blood Coagulation. Dr. Benjamin Alexander. Joseph H. Pratt Diagnostic Hospital.

\*10:00 a.m.-12:00 p.m. Medical Staff Rounds. Peter Bent Brigham Hospital.

12:00 p.m.-1:00 p.m. Clinicopathological Conference (Boston Floating Hospital). Joseph H. Pratt Diagnostic Hospital.

#### MONDAY, FEBRUARY 16

\*12:15-1:15 p.m. Clinicopathological Conference. Peter Bent Brigham Hospital.

## PNEUMONIA AT THE PHILADELPHIA GENERAL HOSPITAL, 1936-1946\*

HAROLD L. ISRAEL, M.D.,† ROBERT C. MITTERLING, M.D.,‡ AND HARRISON F. FLIPPIN, M.D.§

### PHILADELPHIA

IN RECENT years pneumonia has rapidly become less important as a cause of death. There has been a sharp decline in admission of patients with pneumonia to most hospitals and recent studies on the effectiveness of modern therapy of pneumonia have indicated a low case mortality. Nevertheless, at the Philadelphia General Hospital, pneumonia remains a serious problem, and the impression has been obtained that in late years the response of patients with pneumonia to specific therapy has not been so dramatic as that observed in earlier years. The present study was projected to verify this impression, and to determine if possible the responsible factors.

### MATERIAL

The records of adult patients discharged from the Philadelphia General Hospital with the diagnosis of primary pneumonia in three representative years were studied. The year from July 1, 1936, to June 30, 1937, was one in which specific therapy was not available, the year from July 1, 1940, to June 30, 1941, saw the widespread use of sulfonamides and in the year from July 1, 1945, to June 30, 1946, penicillin was available as an adjuvant to or substitute for the sulfonamides.

In an effort to exclude secondary pneumonias, consideration was restricted to patients less than sixty years of age. Cases of tuberculous pneumonia and postoperative and terminal pneumonia were also excluded. In all other patients, the final recorded clinical or pathological diagnosis was employed.

Patients treated in the special pneumonia wards of the hospital, except when admitted *in extremis*, had routine laboratory studies comprising sputum culture, blood culture and complete blood counts. These data are not complete in many cases treated in other wards. Typing of pneumococci was done

routinely in 1936-37 and 1940-41 but, in 1945-46, only 60 pneumococci isolated from blood or exudates. The later years of the study saw increased use of x-ray examination on admission. Other data included the duration of illness and the type of medical care prior to admission, the maximum fever and the incidence of complications. The case mortality rates were calculated both for all admissions and for admissions of patients surviving twenty-four hours. The number of febrile days in the hospital, as well as the total hospital stay of recovered patients, was determined as a further indication of the therapeutic response.

### FREQUENCY OF PNEUMONIAS ACCORDING TO DIAGNOSIS

The total number of cases studied was 368 in 1936-37, 540 in 1940-41 and 420 in 1945-46 (Table 1). In each year approximately 95 per cent or more of the cases were classified as lobar pneumonia or bronchopneumonia. Other bacterial pneumonias, caused by *Klebsiella pneumoniae*, streptococci, staphylococci, *Haemophilus influenzae* and *Salmonella* comprised 4.0 per cent of the total in 1936-37, 1.3 per cent in 1940-41 and 1.4 per cent in 1945-46. The diagnosis of viral pneumonia was made in single cases in 1936-37 and 1940-41, but in the 1945-46 season, similar diagnoses, in this report grouped as viral pneumonias, were made in 14 cases, or 3.4 per cent of the total for the year.

Analysis of the clinical and laboratory characteristics of the two major groups, lobar pneumonia and primary bronchopneumonia, revealed lesser differences than are commonly considered to exist between these two types (Table 2). It appears that the distinction was made in most cases on the basis of the x-ray or pathological report, for the other characteristics did not seem to vary sufficiently to permit a sharp differentiation of the groups. The differences were rather constant, however, in each of the years: patients diagnosed as having bronchopneumonia had a somewhat higher mean age, a slightly longer mean duration of symptoms, slightly less fever and a less marked leukocytosis on admission, sputum culture slightly less often demon-

\*From the Medical Service, Philadelphia General Hospital.

†This study was aided by a grant from The Research Fund for Infectious Diseases, University of Pennsylvania.

‡Clinical associate professor of medicine, Woman's Medical College; associate in medicine, Graduate School of Medicine, University of Pennsylvania; assistant visiting physician, Philadelphia General Hospital.

§Formerly resident in medicine, Philadelphia General Hospital.

strated pneumococci, and positive blood cultures were less frequent in the bronchopneumonias. The frequency of higher types of pneumococci was greater also in this group. The case mortality tended to be higher in the bronchopneumonias, and among the recovered patients in this group the duration of fever and hospitalization tended to be less. It appears that the differences between primary lobar pneumonia and bronchopneumonia in each of the years under study were slight and that the two groups showed parallel changes from one year to the other. These observations indicate the difficulty of clinical differentiation and support the modern tendency to classify the pneumonias on an etiologic basis.

Although on this basis it seems justifiable to combine the two groups for purposes of further analysis, this has not been done since the criteria for diag-

that reported in studies made in the early years of sulfonamide therapy.<sup>2,3</sup> Also notable in the 1940-41 season were the slightly increased mean age of the patients, the reduction in white-cell count and the short duration of fever after admission — the temperature was normal within forty-eight hours of admission in 57.6 per cent of patients receiving specific drug therapy.

There were 312 patients with lobar pneumonia in 1945-46. In 10 cases specific therapy was not received. Sulfadiazine alone was employed in 119 patients, a sulfadiazine-sulfamerazine combination in 34 patients, penicillin alone in 36 patients and penicillin in addition to sulfonamides in 113 patients. Nevertheless, the case mortality failed to show a further decline but rose slightly. The mean age of the patients rose sharply, and leukocytosis was significantly less marked. There was a dis-

TABLE 1 Primary Pneumonias by Diagnosis among Patients under the Age of Sixty

DIAGNOSIS	JULY 1, 1936-JUNE 30, 1937		JULY 1, 1940-JUNE 30, 1941		JULY 1, 1945-JUNE 30, 1946

Totals	368	117	540	64	420	53

nosis of primary bronchopneumonia are poorly defined and are not uniformly applied in all localities. Lobar pneumonia, on the other hand, is commonly considered to be a well defined entity, generally and uniformly recognized. For this reason, the remainder of this investigation is confined to patients with the diagnosis of lobar pneumonia.

The 261 patients with lobar pneumonia in 1936-37 received merely supportive treatment with the exception of 5 cases in which serum therapy was employed. In all respects the clinical and laboratory characteristics of the whole group are typical of those reported in the extensive American studies made before the introduction of serum therapy.<sup>1</sup> The mean age of thirty-five years and nine months, the mean white-cell count of 20,300 on admission and the case mortality of 23.3 per cent are noteworthy because of the changes in these characteristics noted in ensuing years.

In 1940-41 there were 429 patients with lobar pneumonia, 20 of whom failed to receive sulfonamides because of erroneous diagnoses on admission. Sulfadiazine was used in 184, sulfathiazole in 174 and sulfapyridine in 51 patients. Five patients received serum in addition. The sharp decline in the case mortality — to 5.4 per cent — is typical of

tinct increase in mean duration of fever and of hospitalization, the incidence of patients who were afebrile in forty-eight hours was only 39.0 per cent. This was true regardless of the type of therapy used in the hospital. The case mortality varied in a remarkable fashion according to the therapy employed: patients receiving sulfonamides alone had a rate of 1.4 per cent, whereas those receiving penicillin had a rate of 12.0 per cent. This is not inconsistent with the excellent results obtained with penicillin in controlled studies and is merely an indication that all patients recognized as seriously ill received penicillin.

The rise in case mortality of lobar pneumonia observed in 1945-46 is not statistically significant when treated by the chi-square method, but it is remarkable in view of the additional availability of penicillin. There is ample evidence for the effectiveness of penicillin in lobar pneumonia, and the rise in mortality cannot be attributed to the use of penicillin instead of sulfonamides. Actually, the apparent slight increase in mortality was probably not due to chance but rather, as demonstrated below, to alterations in the age distribution of the patients. However, the patients with lobar pneumonia in 1945-46 showed a highly significant difference, the probability that the result was due to chance

being less than 0.0001, from those of 1940-41 in two respects: the decrease in white-cell count and the increased duration of fever after application of specific therapy. A possible explanation for these changes is that an increased prevalence of non-bacterial pneumonias during the war years had resulted in the erroneous inclusion of a considerable number of viroid pneumonias in the group with diagnoses of lobar pneumonia. Another possibility is that a change in the character of pneumococcal lobar pneumonia had occurred.

#### INFLUENCE OF AGE

As pointed out above, the mean age of patients with lobar pneumonia increased from 1936-37 to 1945-46 (Table 2). Table 3 emphasizes this change

remained essentially constant by age groups from 1940-41 to 1945-46. In the latter year, in all age groups except the few patients from ten to nineteen years old, the white-cell count was decidedly lower, and the therapeutic response as measured by critical decline of temperature was considerably less satisfactory (Table 3).

The duration of illness, type of medical care, degree of fever and x-ray findings did not vary consistently with age. The frequency of positive blood cultures was greater in the older age groups.

#### INFLUENCE OF SEX AND RACE

Case mortality rates in 1936-37 showed no remarkable difference between males and females or whites and Negroes (Table 4). Similar observations

†Among patients who recovered.

and indicates that the apparent increase in mortality in the last year was due to the changing age distribution of the patients with lobar pneumonia. It will be noted that in 1936-37 the group of patients from thirty to thirty-nine years of age was the largest, with almost equal numbers in the younger and older groups, in 1940-41 there was a slight increase in the older age groups, but in 1945-46 there was a marked increase, the groups of patients between forty and forty-nine and fifty and fifty-nine each being larger than any of the younger groups.

Analysis by age groups demonstrates the same sharp increase in seriousness of lobar pneumonia with age that was noted in older reports before the introduction of chemotherapy.<sup>1</sup> The use of sulfonamides resulted in a sharp reduction of mortality in all age groups, the case mortality above the age of fifty, however, remained high. Although the rate re-

have been the rule in the past.<sup>1</sup> In the patients receiving specific therapy in 1940-41 and 1945-46, the reduction in case mortality appeared equally striking among white females and Negroes of both sexes, whereas the rate among white males showed a considerably less satisfactory decline. The significantly higher average age of the white males in 1945-46 may have accounted for the high mortality in that year, but the average age of this group in 1940-41 was not markedly higher than that of the other groups. The greater frequency of alcoholism among white males may have been important, although it did not cause a greater mortality in 1936-37.

In both sexes and both races, the decrease in white-cell count and prolongation of fever mentioned above were noted in the 1945-46 group, even though the case mortality was little higher

than in 1940-41. No consistent sexual or racial differences were noted in duration of illness before hospitalization, character of prior medical care, degree of fever or bacteriologic or x-ray studies.

#### SIGNIFICANCE OF WHITE-CELL COUNT

Analysis indicates that the initial white-cell count was not correlated with response to therapy (Table 5). Patients with counts below 5000 showed an extremely high mortality, but the number of such cases was small. With this exception there seemed no constant tendency in any year for the response to therapy to vary with the white-cell count.

In 1936-37 only 12.8 per cent of patients had counts below 10,000, and 45.0 per cent had counts of 20,000 and above; in 1940-41, 15.3 per cent had counts below 10,000 and 36.0 per cent counts of 20,000 and more, whereas in 1945-46 the corre-

a more rapid decline of fever than the patients with moderate or with marked leukocytosis.

The degree of leukocytosis showed no consistent relation with age, sex, race or bacteriologic or x-ray findings.

#### BACTERIOLOGIC EXAMINATION

Sputum cultures were obtained in 67.4 per cent of the lobar pneumonias in 1936-37, in 78.6 per cent in 1940-41 and in 71.6 per cent in 1946-47. In the first of these years, pneumococci were demonstrated either in pure culture or with other organisms in 90.9 per cent, in 1940-41, in 93.2 per cent, and in 1945-46, in 92.4 per cent. The pneumococci isolated from sputum showed considerable variation in 1936-37, Type I, 16.0 per cent, Type II, 10.6 per cent, Type III, 8.9 per cent, Type IV, 1.2 per cent, Type VIII, 1.8 per cent and Type X and higher,

sponding percentages were 31.4 and 20.7. During the decade there have been no changes in organization, procedure, or laboratory personnel that might have been responsible for the changes reported in white-cell counts. A study of the duration of illness prior to admission and of the possible effect of specific therapy prior to hospitalization has been made. These factors do not appear to have been significant (Table 6 and 7), nor did the influence of sulfonamide or penicillin therapy after admission to the hospital appear to have been contributory.

The possibility has been mentioned that the decline in white-cell count, as well as the retarded response to specific therapy, was due to inclusion in the group in which many cases of viroid pneumonias were studied. This possibility is not substantiated by the data in Table 8. The cases with white-cell counts between 5000 and 10,000 would be most likely to include such viroid pneumonias, but this group exhibited the same case mortality and showed

61.5 per cent, and in 1940-41, Type I, 18.9 per cent, Type II, 4.6 per cent, Type III, 13.1 per cent, Type IV, 8.9 per cent, Type V, 3.7 per cent, Type VII, 8.5 per cent, Type VIII, 10.0 per cent, Type IX, 2.7 per cent and Type X and higher, 29.6 per cent. In 1945-46, as noted above, typing of sputum cultures was not done.

Satisfactory blood cultures were obtained in approximately 65 per cent of patients with lobar pneumonia in each of the years under study (Table 8). The percentage of blood cultures reported positive was 20.5 in 1936-37, 20.6 in 1940-41 and 13.2 in 1945-46. In each year the mean white-cell count on admission of patients shown to have pneumococcemia paralleled that of the entire group (Table 8). The case mortality in patients with positive blood cultures was significantly higher than that in other patients. Study of a small group of patients having bronchopneumonia with blood cultures positive for pneumococci revealed white-cell counts and case mortality rates similar to those described above.

The type distribution of pneumococci isolated from the blood in 1936-37 and 1940-41 paralleled that observed in the sputum. In 1945-46 Type II was most often isolated, this may have been the result of the well known high invasiveness of this type, and need not reflect a high incidence of Type II among all pneumonias in this year. It is noteworthy that a positive blood culture was obtained in only 1 of the 44 patients who had received specific therapy, which in most cases was inadequate, before admission.

In the patients with pneumococemia who recovered, the duration of fever was considerably greater than that among patients with other lobar

pneumonias. Again, the duration was longer in 1945-46 — 8.2 days — than in 1940-41 — 6.9 days.

The observation that even among patients with positive blood cultures the white-cell count was much lower and the decline in fever less rapid in 1945-46 than in 1940-41 serves further to eliminate the possibility that these phenomena observed in the entire group of lobar pneumonia were due to erroneous inclusion of viroid pneumonias in the latter group.

#### MEDICAL CARE AND DURATION OF ILLNESS PRIOR TO HOSPITALIZATION

The possibility was considered that the characteristics of pneumonia were modified by the widespread use in recent years of sulfonamides and of penicillin by practitioners treating the patients before admission.

The data presented in Table 6 indicate that only a minority of patients with lobar pneumonia admitted to the Philadelphia General Hospital received medication prior to admission. A history of sulfonamide therapy was obtained in only 11 cases in 1940-41 and in 29 in 1945-46. An additional 4 patients in the latter year received penicillin. Presumably because of this therapy, the patients in this group were ill longer before hospitalization. In other respects, this group did not differ notably from patients not receiving specific therapy before admission.

The mean duration of illness before admission in each year was less in patients who recovered than in those who died. Table 7 indicates that in 1940-41 and 1945-46 this difference was accounted for chiefly by the high death rate among patients who gave a history of illness of a week or more before hospitalization. Surprisingly, there was no increase in mortality with increasing duration of illness prior to admission, provided that this duration was less than a week.

#### X-RAY EXAMINATION

X-ray examination was made in 36.0 per cent of patients with lobar pneumonia in 1936-37, 43.6 per cent in 1940-41 and 85.2 per cent in 1945-46. In many cases the examinations were made in convalescence rather than on admission. Approximately half the examinations were reported to show consolidations typical of lobar pneumonia, the remainder, in most cases, disclosed resolving pneumonia. In slightly less than 5 per cent of cases, a diagnosis of lobar pneumonia was made despite x-ray reports of "patchy" or lobular pneumonia.

#### COMPLICATIONS

The frequency of septic complications fell from 7.3 per cent in 1936-37 to about 4 per cent in the years in which specific therapy was used (Table 9). Invasive pneumococci were apparently as prevalent in the lobar pneumonias of 1945-46 as in those of 1940-41, and it is noteworthy that patients with septic complications did not exhibit the low admission white-cell counts encountered in other patients. In all three years the case mortality in patients with septic complications was very high. Chronic alcoholism, presumably marked, was noted as a complication in 5 per cent of patients in each year. The group consisted predominantly of older white men. Curiously, the alcoholic patients showed no excess mortality in 1936-37 (Table 9), but in 1940-41 and 1945-46 the case mortality was proportionately many times that of the group as a whole. Severe alcoholism is seemingly a major factor in failures of specific therapy in pneumonia.

#### DISCUSSION

The case mortality of lobar pneumonia observed at the Philadelphia General Hospital fell sharply after the introduction of sulfonamides, but no further

reduction occurred after penicillin was made available. The gross mortality appeared to rise slightly in 1945-46 as compared to that in 1940-41, but this was due to the greater proportion of older patients in the more recent year. The declining proportion of young persons is indicative of a lesser incidence or severity of pneumonia among younger patients in recent years.

Two highly significant differences were noted between the patients with lobar pneumonia in

of these criteria, and roentgenologic criteria as well, for the differentiation of these two varieties of pneumonia.

The most plausible explanation for this increasingly ill defined line of demarcation between viroid and bacterial pneumonias may rest in the hypothesis suggested in 1944 by Francis<sup>4</sup> that the picture seen in atypical pneumonia represents the underlying process of most bacterial pneumonias, with the superimposed bacterial infection merely

1940-41 and those in 1945-46 — a further marked decline in degree of leukocytosis on admission, and a retarded temperature response to specific therapy. These characteristics are those of viroid pneumonias, and it seemed possible that the explanation lay in the inclusion in the series by erroneous diagnosis of a considerable number of viroid cases. Detailed analysis indicates, however, that this hypothesis is not tenable. Thus, the same characteristics were exhibited in pneumonias proved to be of bacterial etiology by demonstration of pneumococemia, and patients with

modifying to greater or less degree the basic non-bacterial disease. Such an interpretation obtains support from Hodges and MacLeod's<sup>8</sup> studies on pneumococcal pneumonia in the Army, in which epidemic surges of viral infection and epidemic outbreaks of pneumococcal pneumonia were closely associated. The increasing difficulty in differentiating bacterial and viroid respiratory infections, which is now generally experienced in clinical practice and which Ziegler and his co-workers<sup>7</sup> have documented, may thus be interpreted as being the result of a recent change in the relative intensity of the under-

marked leukocytosis showed the same retarded response as those with normal white-cell counts. It appears that the pneumococcal lobar pneumonias of 1945-46 altered in certain respects from the lobar pneumonias of 1940-41 and earlier. The loss of the characteristic marked leukocytosis and dramatic response to sulfonamides or penicillin deprives us of two criteria that formerly seemed most valuable in the differentiation of bacterial and viroid pneumonias. A recent study by Racker, Rose and Tumen<sup>4</sup> has similarly demonstrated the inadequacy

lying viral and superimposed bacterial infections. The changes observed in lobar pneumonia at Philadelphia General Hospital during the past decade are explicable on the hypothesis that lobar pneumonias represent a heterogeneous group that in recent years has included a larger number of patients in whose disease the bacterial factor was relatively slight.

It is noteworthy that early reports on the use of sulfonamides, as well as of specific serum therapy, emphasized the necessity for early institution of

treatment, whereas the lack of correlation between duration of illness before application of therapy and the case mortality observed in this study is suggestive of a diminishing importance of the bacterial factor

The case mortality rates of lobar pneumonia reported in England and in parts of western Europe prior to the introduction of sulfonamides were considerably lower than the high rates experienced in this country before specific drug or serum therapy was used.<sup>1, 8</sup> This may indicate that pneumococcal lobar pneumonia was not in the past a homogeneous entity and that the viral factor or the bacterial factor, or both, varied geographically

The diminishing importance of the bacterial factor need not be attributed to the influence of sulfonamides and of penicillin. The mortality from lobar pneumonia had declined sharply between 1925 and 1937, to a far greater degree than could have been due to the limited use of serum therapy.<sup>1</sup> As in tuberculosis the decline in pneumonia cannot be explained wholly by the therapeutic advances that have been made, and probably the changes in both diseases are due not to modification of the virulence of bacteria, but to constitutional and environmental factors affecting host resistance

The marked increase in case mortality with age deserves emphasis, for special attention to this factor is required in any evaluation of therapeutic trials in pneumonia. The strikingly low case mortality (less than 1 per cent in lobar pneumonia reported in the Army<sup>9</sup> and the Navy<sup>10</sup>), during the war years is not likely to be duplicated in the general population

The high rates among patients over the age of fifty noted in recent reports from the Cook County Hospital<sup>11</sup> and the Gallinger Hospital,<sup>12</sup> as well as in the present study, and the high rates still observed in patients with alcoholism, empyema, meningitis, endocarditis and pericarditis indicate that the therapeutic problems of pneumonia are not completely solved

#### SUMMARY

A study has been made of lobar pneumonia at the Philadelphia General Hospital in 1936-37, a year in which specific therapy was not employed, in 1940-41, a year in which sulfonamides were generally

applied, and in 1945-46, a year in which penicillin was available as an adjuvant to the sulfonamides. The case mortality rates were 23.3 per cent, 5.4 per cent and 6.5 per cent for the three years, the apparent slight increase in the last year being due to a striking rise in age of the patients

Although the mortality of lobar pneumonia did not vary significantly between 1940-41 and 1945-46, highly significant differences between these years were observed in two respects: a reduction in white-cell counts on admission and a retarded temperature response to specific therapy. Detailed analysis indicates that these changes cannot be attributed to erroneous inclusion in the 1945-46 series of large numbers of viroid pneumonias

It is concluded that pneumococcal lobar pneumonia as observed in 1945-46 had altered significantly from the disease encountered in previous years, and in such fashion that it was clinically difficult to distinguish from viroid pneumonias. It is suggested that lobar pneumonia is not, and has not been, a homogeneous entity but represents rather an underlying viral process modified to greater or less degree by superimposed bacterial infection. The relative importance of the viral and bacterial factors in lobar pneumonia appears to have altered in recent years

## PRINCIPLES OF THE MASSACHUSETTS MEDICAL SOCIETY\*

ELMER S. BAGNALL, M.D.†

GROVELAND, MASSACHUSETTS

THE concept of this symposium came from the late Dr. Michael A. Tighe. He believed that it was time we told each other and the people of the Commonwealth where we are now and where and how we are going.

The following are the principles of the Massachusetts Medical Society as developed by the Subcommittee on Medical Economics and adopted by the Council about a year and a half ago.

The objective of adequate medical care in our free society is to make available to everyone — regardless of race, color, creed, financial status or place of residence — every known essential preventive, diagnostic and curative medical service of high quality. The attainment of such medical care must necessarily be an evolutionary process which will require the co-operation of all concerned over a period of years.

The success of any plan for medical care is dependent on the mutual co-operation of the public, those rendering professional services and the administrative agencies. This co-operation can be obtained only if those rendering the services are convinced that they will have a continuing authoritative voice in the formulation and execution of policies and plans, thereby assuming their proper share of responsibility.

Provision of adequate medical care for those unable to obtain it by voluntary prepayment plans or by direct payment is the responsibility of the local or state government. Part of the burden of this responsibility may be assumed by charitable agencies. Federal grant in-aid to state programs administered by state boards of health is an acceptable method of helping to meet this responsibility.

The medical care of those who are able to purchase it by voluntary prepayment plans or by direct payment is the responsibility of the individual.

Eligibility for receiving benefits under a program aided by federal grants should be determined by the individual states.

The patient shall have free choice of his physician group of physicians, clinic or hospital from among those participating in any plan provided that the physician group of physicians, clinic or hospital shall have the right to refuse or to accept the patient.

Physicians and other qualified persons rendering medical care shall receive adequate remuneration for their services.

The physician shall be free to elect or reject without prejudice participation in a medical-care plan. The rights of the physician as to the choice of methods by which he is to be paid shall be fully protected.

The Massachusetts Medical Society looks upon these basic principles as essential to the development of any successful medical-care plan and, as guides by which to evaluate medical-care plans that may be proposed in the future, with the understanding that changing conditions may require their later revision.

I remember a number of years ago when we, in the Committee of Public Relations, under the able leadership of Dr. Ernest L. Hunt, made some spot studies in adequacy of medical care in this state. I remember in that same committee when Dr. Nathaniel W. Faxon discussed prepayment hospitalization, he stated that such a plan would not

be started without our approval and would proceed only with our approval. I remember that in that same committee discussion of medical-care plans later developed and that, under the brilliant and aggressive leadership of Dr. James C. McCann, the Blue Shield was conceived and launched. At about the same time the White Cross was born. This was an experiment in medical care sponsored by men who were impatient with such "inadequate" concepts for solution of problems in medical-care distribution as the Blue Shield then seemed to them. I have always thought that these men could have performed a service by reporting on the causes of failure factually and objectively.

You will hear today where Blue Cross and Blue Shield stand now. I think that Massachusetts can be proud of its progress in trying to satisfy unmet needs in medical-care distribution. Social changes properly proceed slowly and safely, not at a speed that would satisfy the impatient reformers who blueprint Wagner-Murray-Dingell bills, but fast enough to arouse protests from the ultraconservatives.

The next five years, the next one or two years and perhaps the next few months will be crucial. Change is needed, and with a properly statesmanlike attitude we can provide leadership that will continue to earn us the respect and confidence of a people who have a right to expect leadership from us because we are specialists in the field.

Let us consider casually some of the factors that must be borne in mind as we proceed toward adequate medical care for all the people.

\* \* \*

When we consider adequacy of medical care for all regardless of economic status, we must recognize that there is more involved than rhetoric. Cost is not the chief barrier to utilization of available medical care. For years the Commonwealth has had cancer clinics accessible to all the people that make it entirely unnecessary for anyone to be hoist for long to unrecognized cancer. People still have symptoms for an average of about four months before they seek medical care. There is a great deal in the field of preventive medicine — for example, in tuberculosis and venereal disease — that could be practically eliminated if people would use the facilities for diagnosis and care that are now available. Progress is being made all the time, of course, and the Massachusetts Medical Society is continually doing a great deal toward helping to get medical care of a better quality to the consumer.

\*Presented at the annual meeting of the Massachusetts Medical Society Boston May 30, 1947.

†Formerly president of the Massachusetts Medical Society.

I am very sure that if there were more and better district health councils throughout the Commonwealth tremendous strides would result. The district health council is an organization consisting of representatives of all the facilities and agencies concerned in the distribution of medical care, such as the doctors, the hospitals, the nurses, the druggists, the dentists, the public-health administrators and the social workers. These organizations could analyze the available facilities and see that there is more adequate utilization of those existing, and also supplement these by assisting in the development of services that are deficient.

There is a great need for more utilization of dentists. In England, where government insurance has been in effect for many years, of the 14,000,000 people eligible for dental care, only 7 per cent avail themselves of the service. Massachusetts is still one of the states whose populations have the poorest teeth in the country in spite of a relatively low cost barrier. Very recently Navy medical officers conducted studies of housing, sanitation and health of our coal miners and found conditions that were not satisfactory. These people need better facilities but particularly more education in living standards. Deficiencies even in such fundamentals as running water and indoor toilets exist to a surprising degree. The metropolitan health survey found very recently that there were 100,000 people living in Washington, D. C., without these facilities.

Some planners who sit in ivory towers think that all medical care should be dispensed by groups. There are plenty of good reasons why more group practice should be carried on, but that will develop better by evolution—through trial and error. Groups were more popular for a while after World War I, but there were many failures and only a few brilliant successes. Time does not permit analysis of the causes of failure. The general practitioner is the backbone of the system of distribution of medical care to the people, and I hope that he always will be. I am willing to debate this with anyone who does not agree. The general practitioner is as essential to medicine as the infantryman is to the army. Every general practitioner has his own informally organized group. He knows who among those available is the best qualified for the patients who need a specialist. It is only relatively few who need specialized diagnostic care or treatment. It is not good economy to consult the specialist for everything. There is a degree of obligation in organized groups to utilize only group personnel. This limits choice too much in some cases.

There are a group of people—the medical indigents—who are able to meet the expenses of ordinary medical care but once in a few years are confronted by unusual diagnostic costs and perhaps surgery and hospitalization. These people vary in number with the degree of prosperity in the country. But they are enough of a problem so that it seems

probable that ultimately the only logical way to meet the cost is by governmental subsidy. Many of those who would have been medically indigent have been lifted out of that group by being able to pay for medical care through Blue Cross and Blue Shield. I have patients who were formerly unable to pay for obstetric care and are now proud that they can meet these costs in this way. I have figures that indicate that in a one-hundred bed hospital the doctors on the ward services contribute more than \$100,000 a year in medical and surgical services to the community. We have done very little complaining about this. Many people think that we are paid a salary for these services.

The Taft Bill (S 545) proposes to have the federal Government subsidize the state to take over this burden. It would be essential to have a continuing authoritative voice given to the doctors in the management of the professional side of such a plan. In England, under a new plan, the Labor Government has taken over medicine and the hospitals lock, stock and barrel. The importance of proper technical advice from the doctors has not been realized. There is an advisory board, but it has been given no power, one of the medical statesmen of England recently said, "You know that kind of a board can cut no ice." The Massachusetts Department of Public Health appreciates the necessity of co-operation with technical advisory boards. The Department of Public Welfare is beginning to learn. Federal financing means that the federal Government will need to raise the money, federal money comes from the taxpayers, and Massachusetts pays a good share of federal taxes. We approve of the principle of taxing Massachusetts more to provide for some of the poorer states—in the same way that we who are better able to bear the tax burden take care of the poor in our own town.

The physician should receive adequate remuneration for his services. The cost to the medical schools for education is about \$2400 per year per student. One New England school a few years ago had \$5000 in the budget per medical student per year. Dr. Elliott P. Joslin states that the average doctor in the Commonwealth practices only fifteen years. The man or woman who goes to college for four years and to medical school for four years has to spend at least \$10,000 of somebody's money for his education. Then he has from two to five years' training in a hospital before he begins to pay off the mortgage. He has barely time to get a proper basis for living for his family and enough insurance to keep them from becoming public charges before his years of usefulness are waning. Certainly, those who know the facts do not expect the doctor to do the job he does for less money.

The Massachusetts Medical Society has a few leaders who have constantly tried to discover and meet the medical needs of the Commonwealth and

of the country. As we come into these times of more active social adjustment we have made very considerable strides in better organizing ourselves to serve the people. We might have done a good deal more in the past, but too many of us have been too busy meeting the needs on the firing line, moreover,

social changes develop along sounder lines if the whole body politic has a chance to get conditioned to change at an evolutionary rate. It is axiomatic that the best that is known is ahead of the best that is done in this as in all fields.

## WHO CARES FOR THE EPILEPTIC?\*

WILLIAM G. LENNOX, M.D.,† MERLE McBRIDE, A.B.,‡ AND GERTRUDE POTTER§

BOSTON

**E**PILEPSY is a larger public-health problem than is generally realized, even by doctors. Its supposed infrequency is due to the practice of concealment and to the widespread popular belief that for epilepsy there is no effective treatment. The United States Selective Service figures of 1917 gave for Massachusetts an incidence of 0.59 per cent (as compared with 0.515 for the whole country). Yet medical officers know that thousands of epileptic patients were not detected by the Selective Service examinations, thousands risked a lie to risk a life for their country (and the esteem of their fellows). If the statistics are accepted, epilepsy is as common as active tuberculosis, diabetes or crippling infantile paralysis.

In Massachusetts, how many epileptic patients are supervised medically? How many are cared for in clinics, and how many in private offices? How is the burden distributed among practitioners and the various specialists? Do physicians wish for additional information about epilepsy and newer methods of therapy? In the summer of 1946 the Committee on Public Health of the Massachusetts Medical Society, which is commissioned by the Society to "foster the knowledge of disease by any appropriate measures," sent a letter to each member of the Society asking for information that would help to answer these questions. The American Epilepsy League inspired the effort. Expenses were met by the Bay State Society for the Crippled and Handicapped, which helps to support the Seizure Unit of the Children's Hospital of Boston. Letters went to 5539 physicians. Of these, 2997, or 54 per cent replied to either the first or a follow-up letter. Deducting 201 replies from men who were in, or just out of, service, 2796 blanks remained.

### Patient Load

The questionnaire asked for the number of epileptic patients who had been seen privately or in

clinic during the previous twelve months. Of the physicians replying, 1613, or 58 per cent, had "seen" epileptic patients in the past year, and 1183, or 42 per cent, had not. Of the 1613 doctors who treated these patients, 1472, or 91 per cent, did so in private offices, and 316, or 19 per cent, in a clinic. Ten per cent saw patients in both places.

Doctors were asked the approximate number of epileptic patients seen in the year. 11,434 patients were reported, of whom 60 per cent were office and 40 per cent were clinic cases. This does not include 2746 patients cared for in institutions. The numbers are exaggerated because a given patient may have visited more than one physician or may have been seen both as a clinic and as a private patient.

### Distribution of Patient Load

The 1472 doctors who reported office treatment of epileptic patients during the year saw a total of 6905 patients, or an average of 4.7 each. The much smaller number of doctors, 316, saw a total of 4529 patients in a clinic—an average of 14.3 per doctor. If the total number of noninstitutional ("extra-mural") patients are divided equally among the doctors who treated patients, the number per doctor is 7.1, of which 4.3 are office and 2.8 clinic cases. If the 11,434 patients are divided among the 2796 "active" doctors answering the questionnaire, the distribution is 2.5 office and 1.6 clinic, with a total of 4.1 patients. Probably each physician who returned the questionnaire treated more epileptic patients than those who consigned it to the wastebasket. Assuming that the 46 per cent of doctors who did not return the questionnaire saw only half as many of these patients as those who did, the stated number of epileptic patients, on the basis of equal distribution among the 5338 physicians, provides each with three patients. This number is undoubtedly too high because of duplication. Patients reported by the heads of x-ray departments and other laboratories were eliminated because they would have been reported also by the referring physician, but other duplications could not be detected without a request for the names of patients. The incidence of epilepsy among men examined for

§President, American Epilepsy League.

the Army in 1917 would give Massachusetts approximately 20,000 epileptic patients, or something like 4 patients to each doctor. Probably not more than half this number were seen by the doctors in Massachusetts during the year in question. This conclusion will not surprise those who examined Selective Service registrants in the last war. Many acknowledged patients had not consulted a physi-

FIGURE 1 Number of Epileptic Patients Seen for Each Doctor Answering the Questionnaire

cian, believing that doctors could offer no effective treatment.

### Patient Load and the Specialties

Physicians were asked to name their specialty. The number of patients treated annually by practitioners and various specialists is shown in Figure 1. As would be expected, the group of neurologists,

groups presented in Figure 1, all but two saw a little more than half of the epileptic patients privately (from 54 to 59 per cent). The two groups that were far outside this zone were the general

FIGURE 2 Distribution of Epileptic Patients among Groups of Doctors

The columns represent the proportion of the total of 11,434 patients who were seen by the specified doctors. The horizontal lines give the proportion of the total of 2796 doctors who belong to each specialty. The hatched columns represent patients seen privately, and the dotted columns those seen in clinics.

practitioners, with 89 per cent office patients, and the pediatricians, with only 29 per cent of patients seen in the office and 71 per cent seen in clinics. Since clinic work carries little or no monetary reward, pediatricians must be carrying a disproportionate share of the charity load. Whether this

TABLE 1 Distribution of Office and Clinic Patients among Various Groups of Doctors

Totals	2,796		6,905		4,529		11,434	

psychiatrists and neurosurgeons heads the list, with an average of 32.8 patients per doctor (the five neurosurgeons who reported had an average load of 68 patients). Next in importance are the pediatricians, who saw an average of 12.5 epileptic patients. Aside from these two groups—numbering only 233 doctors—the internists, general practitioners, surgeons and other specialists saw, respectively, from 3.7 to 1.3 such patients in the year.

In view of the present agitation for lower cost of group treatment of patients, comparison of the numbers of patients treated as private and as clinic patients deserves special attention. Of the six

preference of the parents of the epileptic child for the clinic is due to economic conditions or to a belief as a result of publicity that better treatment can be obtained in the clinic is not clear from this survey. The survey of pediatric service now going forward should demonstrate whether other diseases of children tend to receive care in clinics at the expense of office practice.

The preceding data may give the impression that the care of epileptic patients is in the hands of neuropsychiatrists and pediatricians. Study of the share of each specialty in carrying the total patient load demonstrates the incorrectness of this view.

Neuropsychiatrists, neurosurgeons and pediatricians treated only 37 per cent of office and 47 per cent of all patients. This is because these specialties constitute only 9 per cent of the doctors who responded to the questionnaire. The essential data are presented in Table 1. The columns of Figure 2 represent the distribution of extramural patients among the six groups of doctors, and the horizontal lines indicate the distribution of the doctors themselves. Thus, at the left of the figure, neuropsychiatrists number but 4 per cent of the number of doctors replying, but they saw 34.5 per cent of the 11,185 patients reported and, although each treated fewer clinic than office patients (Fig. 1), they saw a larger proportion of the total clinic cases than of the total office patients. The general practitioners carry the next largest load — namely, 35 per cent of office and 24 per cent of all patients. Practitioners and internists combined saw approximately half (49 per cent) of all office patients. The neuropsychiatrists and pediatricians combined saw 62 per cent of clinic patients. A comparison of the height of columns and of the solid line in Figure 2 displays the proportion of patients seen by various groups of doctors in relation to the numbers of doctors in these groups. Thus, neuropsychiatrists and pediatricians saw a large proportion of patients in relation to their own meager numbers. Surgeons, practitioners in clinics and other specialists saw relatively few epileptic patients. This tabulation, like that of Figure 1, emphasizes the relatively large clinic load carried by pediatricians. They receive relatively small recompense for the work of this nature that they do. As would be expected, various specialties such as the eye, ear, nose and throat, orthopedic and skin take care of relatively few patients with epilepsy.

#### *Physician Interest in Newer Knowledge*

The degree of mistreatment of a given patient is measured by how far the given therapy falls short of utilizing the best possible methods. On each accession of knowledge a previously "good" form of therapy becomes mistreatment, or at least inadequate. The same statement is as true of social as of drug therapy. For many centuries effective medical and surgical therapy was nil. Discoveries of the last ten or twelve years mean as much for the present-day epileptic person as the discovery of ether meant to the surgical patient a century ago. Yet, as neurologists of the Selective Service boards who questioned the raw mass of young men can testify, many patients with the Hippocratic disease either receive no care or treatment little better than that prescribed by Hippocrates himself. Massachusetts may be called the home of electroencephalography, of modern anticonvulsive therapy, or research and of interest in the disorder. Massachusetts has facilities for the care of epileptic patients unequalled elsewhere: the headquarters of

the International League Against Epilepsy and of the American Epilepsy League, a dozen electroencephalograph laboratories, the Monson State Hospital, a national center for treatment and research at the Cushing Veterans Administration Hospital and special clinics for epilepsy in several hospitals. Unfortunately, facilities are too much concentrated in Boston. The New England Epilepsy League hopes to learn of physicians in New England who are both interested and competent in handling epileptic patients. The diagnostic, research and training center recently established at the Children's Hospital in Boston with the aid of the Bay State Society for the Crippled and Handicapped plans an extension of its services to physicians, hospitals and social agencies throughout the Commonwealth. Like charity, the application of medical knowledge does not always begin at home, and probably only a minority of the epileptic patients of Massachusetts are today receiving adequate medical and social care.

Social therapy is even more antiquated than medical. Twenty-six per cent of the colleges and universities of New England have a blanket rule against admission of scholastically qualified but epileptic students, the great and good Massachusetts General Hospital, birthplace of medical social service, will not engage a person who has a history of seizures, and the great Commonwealth of Massachusetts with a law that allows a handicapped worker to waive his rights to accident compensation will not extend that privilege to epileptic patients, nor will it permit the physician to give contraceptive advice to his epileptic patient who wants marriage but not children. Fourteen states of the Union forbid the epileptic person to marry, and the United States Government subjects the epileptic patient who comes to this country for medical advice to an embarrassing delay on Ellis Island.

To meet the need of doctors, social agencies and patients for up-to-date information about epilepsy and its medical and social therapy, the American Epilepsy League has assembled a series of medical reprints and popular articles, as well as several books. With the original questionnaire went a list of twelve of these articles and several books. Physicians were asked to check those desired. Of the 785 doctors who answered the first letter, 578, or 73 per cent, requested one or more reprints. The proportion was 80 per cent of the 434 doctors who saw patients, and 58 per cent of the 144 doctors who did not. These 578 doctors asked for three thousand, two hundred and thirty-three pieces of literature, or 5.6 per doctor. This average number was 5.9 for doctors who saw epileptic patients and 4.5 for those who did not. Of all articles requested, 73 per cent were technical, and 27 per cent popular — for the benefit of patients and their friends and relatives.

## SUMMARY

Backed by the Committee on Public Health of the Massachusetts Medical Society and the Bay State Society for the Crippled and Handicapped, the American Epilepsy League sent questionnaires to all members of the Medical Society. Of 2796 doctors replying, 58 per cent had treated epileptic patients during the previous year. Of these, 91 per cent saw them in the office, 19 per cent in the clinic, and 10 per cent in both office and clinic. Of the 11,434 patients treated, 40 per cent were clinic and 60 per cent were office patients. Equally distributed, there would be 41 patients for each doctor who returned the questionnaire. Taking into account the duplication in this survey, probably not more than half the estimated 20,000 epileptic persons in Massachusetts are receiving active medical supervision.

Among all doctors replying, the average neuropsychiatrist or neurosurgeon saw 33 patients, the pediatrician 12, and other specialists and general

practitioners from 37 to 17 each. Pediatricians treated 71 per cent of their epileptic patients in clinics, whereas all other doctors saw only 33 per cent there. Of all epileptic patients treated privately, the general practitioner saw the largest proportion—35 per cent, 31 per cent were seen by neuropsychiatrists, and 14 per cent by internists. Of all clinic patients, 40 per cent were seen by neuropsychiatrists, 22 per cent by pediatricians and 15 per cent by internists. Pediatricians constituted only 5 per cent of the doctors who reported, but they treated 22 per cent of all clinic patients. They bear an unusually heavy load of charity patients. Of the 785 doctors who responded to the first questionnaire, 73 per cent requested reprints of articles on epilepsy, of which 73 per cent were technical in nature. Study of the questionnaires returned, together with our general experience, convinces us that both medical and social treatment of epileptic persons in Massachusetts and other states falls far short of utilizing knowledge gained during the past dozen years.

## A STUDY OF VIRUS CARRIERS FROM A POLIOMYELITIS OUTBREAK AT A BOYS' CAMP\*

A DANIEL RUBENSTEIN, M D,† J PERSIS MILNOR, M D,‡ HERDIS VON MAGNUS, M D,§ AND JOSEPH L MELNICK, PH D ¶

BOSTON, MASSACHUSETTS, AND NEW HAVEN, CONNECTICUT

**S**MALL, localized outbreaks of poliomyelitis offer unusual opportunities for epidemiologic study. The more isolated the population unit under observation, the less complex appears the task of tracing chains of infection. However, it remains for future discoveries to determine how true this may actually be so far as poliomyelitis is concerned.

A recent outbreak of poliomyelitis in a boy-scout camp in western Massachusetts seemed to be particularly well suited for epidemiologic study. In the first place, prior to its occurrence, no cases of infantile paralysis had been reported from all of western Massachusetts for three months. Furthermore, the location of the camp near the summit of an isolated mountain reservation reduced the opportunity for outside contact of campers and personnel, although the camp cannot be described as a truly "isolated community."

Investigation of this outbreak was instituted after the rather sudden occurrence of 3 cases at the camp in July, 1946, when it was decided to disband the organization. Nearly all personnel returned home, with the exception of 20 persons who, for one reason or another, remained behind. Those events are presented graphically in Figure 1.

The plan of the study was to determine the carrier rate in the group of campers who were most heavily exposed to, or perhaps together with, known cases, as measured by virus isolations from throat and stool cultures.

It was believed that a number of features could be learned from this approach. Recent investigations have demonstrated that the poliomyelitis virus may be isolated more readily from stools than from material obtained from the oropharynx of patients<sup>1</sup>, however, observations on the relative frequency of intestinal as opposed to throat carriers among healthy contacts are few in number<sup>2,3</sup>. It was proposed in this study to compare unpooled serial specimens (throat swabs and stools) obtained from contacts over a period of several weeks. Furthermore, since it is not known how often healthy carriers may directly transmit virus to others, investigation of children in households to which exposed campers

returned also presented a limited opportunity to acquire new data on this point

### MATERIAL AND METHODS

The camp in western Massachusetts is referred to as Camp Pfd. Since all the clinical cases of poliomyelitis appeared in one of three groups of campers, it was decided to develop the laboratory investigation with this one group as the focal point. Because the camp had been dispersed at the time the study was begun, the aid of the local health department and visiting nurses\* was sought in obtaining laboratory specimens. From the time of the out-

The blood was centrifuged, usually on the day of collection (or within twenty-four hours during which it was kept in the icebox). Serum was drawn off and frozen †. All material was kept frozen, even during transport to New Haven, until it was prepared for animal inoculation or testing.

**Virus testing.** In general the methods followed have been described in previous communications from this laboratory.<sup>1,4,6</sup> Throat specimens were prepared for intracerebral inoculation by elution from the swabs and subsequent etherization.<sup>6</sup> Stools were also inoculated intracerebrally after their processing in the ultracentrifuge.<sup>4</sup> Rhesus (*Macaca*

FIGURE 1 Occurrence of Clinical Poliomyelitis at Camp Pfd in Relation to Camp Population.

break, throat swabs and stool samples were obtained three times a week for four weeks from 18 of the 26 members of this group. Whenever possible, similar specimens were also taken from children in households to which exposed campers had returned. For serologic studies, each of the selected group of campers and their household contacts was subjected to three bleedings, one at the time of the initial visit and two others at intervals of three weeks. Blood, throat and stool specimens were also obtained from 7 other campers who were not members of the group in which the clinical cases occurred.

Throat swabs were placed in 1 cc. of water in a dusteroid tube and frozen immediately after being obtained. Stools were also frozen as soon as they were collected by the health-department personnel.

\*Misses Ann M. Thompson, R.N., Charlotte Cornwell, R.N., Beulah Zilling, R.N., and Justine Baldissarotto, R.N., helped in the collection of these specimens.

*mulatta*) monkeys were used as test animals — as a rule, one monkey being utilized for each test. All positive results for virus were confirmed by histologic findings of typical lesions in the spinal cords.

**Neutralization tests.** These were carried out with the Lansing and Y-SK murine-adapted, monkey-pathogenic strains of poliomyelitis virus. The technic was similar to that outlined by the Commission on Neurotropic Virus Diseases of the Army Epidemiological Board,<sup>7</sup> constant amounts of virus being used with varying dilutions of serum.

### EPIDEMIOLOGY

The camp grounds covered an area of several acres and were located near the summit of a mountain (elevation, 1930 feet) in Berkshire County,

†We are indebted to Dr. H. Lee M. Scoville, House of Mercy Hospital, Pittsfield, for her aid in preparing the serum.

Massachusetts Tents were placed in three areas, each about 50 yards in diameter and 100 yards from each other. Another section of the camp site was set aside for a screened kitchen cabin, unscreened mess and utility tents, an infirmary, several odd cabins and tents occupied by members of the staff. Swimming and water sports were carried on in a fresh-water lake several acres in extent, located below the level of the rest of the camp.

The personnel of the camp was divided generally into four groups, three of campers (Rangers, Pioneers and Blue Moccasins) and one staff group. The ages of the campers ranged from twelve to eighteen

TABLE 1 *Date of Arrival and Onset of Cases*

CASE No	DATE OF ARRIVAL AT CAMP	DATE OF ONSET
1	July 7	July 17
2	July 7	July 18
3	June 23	July 21
4	June 30	July 26
5	July 7	July 29

years. There was no sharp division regarding home town or date of arrival at camp.

Sports and the daily routine were carried on by groups. However, on occasion all campers participated in general activities. Meals were eaten by all campers and the staff simultaneously in a common dining room, but each of the groups ate at a separate table. Although all the food from the camp kitchen was distributed equally among the three groups of campers, some additional food was brought in on Sundays by relatives and friends. This food was generally distributed by campers only to members of their own group. This was but one of the indications that in spite of the isolated location, the community was in close touch with the outside world.

The Ranger and Pioneer groups were housed in large tents, 8 campers being assigned to each tent. The leaders and counselors for each of these groups were in two-man tents. The campers and counselors of the Blue Moccasin group were housed in seventeen tents, each tent housing 2 persons. Sewage disposal was by pipe and pit urinals and by pit latrines covered with unscreened boxes. Garbage was carried away from the camp grounds and disposed of. The milk was pasteurized and of good quality, and arrived in 40-gallon cans. At mealtime the milk was poured into pitchers for individual tables. The food was obtained from recognized sources, and all perishable foods were kept on ice. The water supply came from a tubular well, and tests revealed it to be free from bacterial contamination.

The first group of about 20 persons, consisting of staff members, counselors and junior leaders, arrived in camp on June 23, 1946 (see Fig 1). The first contingent of campers, comprising more than

50 boys arrived on July 7, when some of the first group returned home. A third group of approximately 35 campers arrived on July 13, when 30 of the original campers went home. With the exception of 20 persons, all personnel returned home between July 20 and 23.

According to the infirmary records, between July 12 and 16 there occurred 6 cases of minor illnesses in which the diagnosis was indefinite but the signs and symptoms were compatible with suspected (abortive) poliomyelitis. Although this diagnosis was not considered at the time, the patients were seen to be ill by the camp nurse. There were two small epidemics of diarrhea, primarily among the Pioneer group during the first two weeks of camp, and, in addition, a number of upper respiratory infections involving about 30 per cent of the camp population throughout the entire time of its operation.

The distribution of cases of infantile paralysis, according to the day of onset and the time of arrival at camp of each patient, is shown in Table 1. Cases 1, 2 and 5 had arrived in camp on July 7, and Cases 3 and 4 on June 23 and 30 respectively. They all became ill between July 17 and 29.

As stated above, all 5 cases occurred among 31 boys who were members of one group, the Blue Moccasin group, between July 7 and 14. Cases 1 and 5 were tent mates, both boys lived in the same town, Great Barrington. Patients 2, 3 and 4 resided in Pittsfield, another nearby town. No cases of infantile paralysis had been reported from either community since 1945. Not a single member of either the Pioneer or the Ranger group developed clinical poliomyelitis. Of the 5 cases, a diagnosis of bulbar poliomyelitis was made in 4. One patient died because of involvement of the respiratory center, and another received care in a respirator for a period of several months.

#### RESULTS OF LABORATORY INVESTIGATION

##### *Establishment of the Strain of Virus and Attempt at Identification*

The strain was first isolated readily from the pooled fecal specimens obtained from 3 of the hospitalized patients (Mo, He and La). Three serial passages of the virus in monkeys were carried out, and attempts were made with central-nervous-system material from each monkey passage, as well as with infective human stools, to adapt the virus to mice and cotton rats. Whereas the strain took easily in monkeys, no evidence of disease was seen in the rodents, even when such technics as concentration in the ultracentrifuge,<sup>8</sup> blind passage and Milzer's autolyzed brain method<sup>9</sup> were used.

Although the Pfd camp strain has not proved to be pathogenic for rodents, attempts were made to determine whether it was related immunologically to the Lansing and Y-SK strains. Convalescent and

hyperimmune monkey serums were prepared for the camp strain, and neither serum neutralized Lansing or the Y-SK strain.

Thus, the Pfd strain of virus appears to be typical of the usual type in the experimental disease produced in monkeys and in its failure to take in rodents. Moreover, no relation was demonstrated between this strain and the Lansing and Y-SK strains. These strains were both isolated several years ago, the former from the brain of a fatal case in Lansing, Michigan,<sup>10</sup> in 1938, and the latter from the stool of an abortive case in New Haven, Connecticut,<sup>11</sup> in 1937.

### Carrier Rate among Campers

An attempt was made to determine the carrier rate among the healthy members of the Blue Moc-

casin group. It may be assumed that the latter campers had the same opportunity for exposure as those who developed poliomyelitis. There had, of course, been contact between them. These data are presented in Table 2.

One of this group from whom specimens were collected developed the first symptoms of poliomyelitis one day after the first collection of samples. Both the stool sample and the throat swab collected at this time from this boy (Fi) contained poliomyelitis virus.

Of the remaining members of the group, 5 virus carriers were found among 18 boys tested. All 5 were intestinal carriers, and only 1 of the 5 was

found to harbor virus in the throat. None of them gave a history of symptoms compatible with the picture of mild poliomyelitis.

Of these 5 carriers, 3 were found to be excreting virus in the stools for a period of at least three or four weeks. Whereas the patient (Cu) who was both a throat and intestinal carrier excreted virus in the stool for about a month, virus could no longer be found in the throat after the first week. These

findings are analogous to those encountered in similar studies on the frequency and duration of virus carriers among patients with clinical poliomyelitis<sup>1</sup> and in a similar camp group of healthy contacts.<sup>2</sup>

A small control group of 7 Pfd campers, not belonging to the Blue Moccasin group, were also tested. No intestinal carriers were found among them.

### Carrier Rate among Secondary Contacts

Since the camp was officially closed and the boys sent home soon after cases occurred at the camp, an opportunity existed for studying secondary familial contacts, especially those of virus carriers.

Of the 5 healthy carriers, only 2 had siblings at home. Throat swabs and stools from both these siblings were collected over a period of a month. None of this material contained virus. It is of interest that one of these secondary contacts was exposed to a carrier harboring virus in the throat as well as in the intestinal tract.

### Antibody Response to Murine-Adapted Strains of Virus

Although the Pfd strain did not appear to be related to the Lansing or Y-SK murine-adapted strains, neutralization tests in mice were carried out with the latter strains on serums from campers representing 3 healthy carriers of virus and 3 healthy controls who had been found not to be carriers of virus. Although neutralization tests with these murine-adapted strains had been carried out on hospitalized patients in other epidemics, antibodies had not here-

tofore been looked for in paired serums of healthy carriers collected early and late in relation to the time of virus excretion

No significant change in antibodies to the murine-adapted strains as a result of exposure to the outbreak was demonstrable (Table 3). One of the carriers had no humoral antibodies and failed to develop any during the period of exposure. The serums of the other 2 carriers both contained antibodies at the time virus was first detected in the stools. There appeared to be a slight rise of questionable significance six weeks later.

Of the 3 healthy noncarriers of virus, 2 did not have humoral antibodies, nor did any develop during the interval of three to six weeks between collections. The third member of this group, on the other hand, maintained a constant antibody level during the six-week period.

### DISCUSSION

The attack rate in one group (the Blue Moccasin group) of Pfd campers was high. Of a total of about 31 campers, who were all, so far as is known, similarly exposed, 5 developed frank poliomyelitis, and of 18 healthy members of this group, 5 were found to be carriers. (The remaining 8 members were not available for study.) This gives a frank attack rate of about 5/31 (or 16 per cent) and an infection rate of 10/23 (or 43 per cent). This high incidence of disease was recognized only among the Blue Moccasin group, no cases occurred in the two other groups living under almost the same conditions.

Of the 5 carriers, 3 excreted the virus in the stools for at least three or four weeks. These findings are analogous to those encountered in similar studies on the frequency and duration of virus carriers among patients with clinical poliomyelitis. Further study is necessary to determine the possible epidemiologic significance of the prolonged period of excretion of the virus from the intestinal tract. Of the 5 carriers who returned to their homes, only 2 had siblings there. Throat swabs and stool samples were obtained from both these children, and all samples gave negative tests in monkeys. It was unfortunate that this part of the study was so limited as to render our few negative results of no statistical significance.

Similarly, the serologic studies were disappointing, for the homologous strain was not used. In other words, the Pfd strain was not found to be related to the Lansing and Y-SK strains. Had the serologic studies been performed with the Pfd camp strain, an entirely different result might have been obtained. This was not feasible because of the failure of this strain to be adapted to rodents.

### SUMMARY

An outbreak of infantile paralysis in a boy-scout camp attended by boys aged twelve to eighteen years is described. Although the camp was divided into three groups the occurrence of clinical cases was confined to only one of the groups, and the carrier-rate studies were similarly confined to this group.

Of the 31 members of this group, 5 developed frank poliomyelitis, with 4 bulbar cases, 1 of which terminated fatally.

Of the 18 healthy members studied in this group, 5 were revealed to be intestinal carriers of virus, and 1 of these also harbored virus in the throat.

Estimates of the total infection rate in this group were roughly 43 per cent, with a ratio of frank cases to carriers of about 1/2.

Of the 5 carriers, 3 excreted the virus in the stools for at least three or four weeks.

In the single carrier in whom the virus was isolated from both the oropharynx and the intestinal tract, virus was isolated from the stools for a period of about one month, it could not be found in the throat after the first week.

In 1 of the clinical cases, virus was isolated from both the oropharynx and the stools one day before the onset of symptoms.

Of 2 siblings exposed to virus carriers (1 of whom had virus in both the throat and stools), neither subsequently became virus carriers.

The strain of poliomyelitis virus isolated during the outbreak did not appear to be related to the Lansing and Y-SK strains by serologic test, nor could it be adapted to rodents even after many trials.

## MEDICAL PROGRESS

## THE "NEPHROTIC SYNDROME"\*

STANLEY E. BRADLEY, M.D.,† AND CORNELIUS J. TYSON, M.D.‡

NEW YORK CITY

THE "nephrotic syndrome" is one of the most striking phenomena of renal disease. The combination of gross edema, hypoproteinemia, hypercholesterolemia, lipidemia and heavy proteinuria, in the absence of congestive heart failure, is unique and easily recognized. It frequently appears during the course of chronic diffuse glomerulonephritis (the nephrotic phase).<sup>1</sup> Other causes are renal amyloidosis, syphilis, intercapillary glomerulosclerosis and renal-vein thrombosis. In children and young adults the syndrome occasionally develops in the absence of renal disease as so-called "pure," "genuine" or lipid nephrosis. A prolonged debate has centered about this entity. It is claimed on the one hand that the disorder is renal in origin, either a disease entity *sui generis*<sup>2,3</sup> or the result of an unrecognized glomerulonephritis,<sup>4,5</sup> and, on the other, that it is primarily extrarenal, perhaps on the basis of some obscure derangement of protein metabolism.<sup>6,7</sup> Conflicting opinions regarding the pathogenesis of various manifestations are likewise unsettled, but there is general agreement that the "nephrotic syndrome" presents certain uniform and consistent features, whatever its etiology. The following discussion is devoted chiefly to a consideration of these aspects of the disorder.

## PROTEINURIA

One of the most impressive and characteristic manifestations of the nephrotic syndrome is the continuous loss of large amounts of protein in the urine. The resulting drain upon body protein and the stimulus to increased protein synthesis probably contribute in the pathogenesis of various associated phenomena, but unfortunately, too few unequivocal facts are available at present to permit an analysis of the situation as a whole. Indeed, the nature and source of urinary protein is still debated, and current concepts of the renal mechanism of protein excretion are speculative.

Analysis of proteins in blood and urine is handicapped by the lack of satisfactory methods for isolating pure components of the protein mixture. Fractional "salting-out" precipitation has been used for separating albumin from globulin. It is now known that these fractions are heterogeneous. The use of ultracentrifugation, electrophoresis and im-

munologic techniques indicates that at least five globulins and two albumins are distinguishable,<sup>8-12</sup> and it is believed by those intimately engaged in the work that even the refined fractions are not pure.<sup>14</sup> As Gutman<sup>15</sup> points out in an excellent review, the discovery that albumin obtained by fractional precipitation contains significant amounts of globulin is very important, since changes in the globulin content of the albumin fraction may account for apparent deviations from the normal.

The plasma protein composition is greatly altered in the nephrotic syndrome. All methods agree in revealing a marked reduction in albumin.<sup>16,17</sup> The globulin content may rise, especially in amyloidosis,<sup>18</sup> remain unchanged or fall.<sup>17,19</sup> Usually, the beta globulin and fibrinogen increase, the alpha globulin may rise when the albumin concentration is very low. Gamma globulin is almost always reduced.<sup>18</sup>

There is no reliable evidence that the plasma contains abnormal proteins. Plasma albumin, separated by precipitation, has a somewhat higher molecular weight and lower osmotic pressure than normal,<sup>19,20</sup> presumably because there is a larger proportion of contaminating globulin. Differences in fractions obtained by ultracentrifugation may also be explained on this basis.<sup>21</sup> Specific antisera to plasma albumin and globulin fail to precipitate nephrotic proteins quantitatively suggesting the presence of immunologically distinct proteins.<sup>8,22,23</sup> But it now appears that the unprecipitated portion of the albumin fraction is in reality globulin precipitated with the albumin during salting out. An abnormal distribution of globulins differing antigenically may be the cause of the anomalous behavior of nephrotic globulin.<sup>8</sup> Alving and Mirelsky<sup>24</sup> found that nephrotic plasma from which globulin had been removed by precipitation contains less cystine than normal. They attributed this to the appearance of a cystine-poor albumin, from which normal albumin could be removed by recrystallization. It has recently been shown,<sup>25</sup> however, that alpha globulin, the usual contaminant, contains very little cystine, and it now seems likely that the authors were dealing with this component and not with an abnormal protein.

Albumin preponderates in the urinary protein mixture. The electrophoretic pattern may resemble the pattern of normal plasma in showing a very large albumin peak even when plasma albumin is markedly depressed.<sup>19,26</sup> In some cases globulins may

\*From the Department of Medicine (Columbia University College of Physicians and Surgeons, and the Presbyterian Hospital).

†Assistant professor of medicine, Columbia University College of Physicians and Surgeons; assistant attending physician, Presbyterian Hospital.

‡Assistant resident, Presbyterian Hospital.

be prominent, apparently as a result of more extensive and severe renal damage.<sup>27</sup>

Evidence that abnormal proteins may appear in the urine has been vitiated by the failure to work with pure homogeneous fractions. It is interesting that the "abnormal" albumin detected in the urine by specific antisera, by high molecular weight and by low cystine content is always present in lower concentration than in the plasma.<sup>19, 21</sup> Proteins of small molecular size predominate in the urine,<sup>19</sup> and it is consistent with this tendency that the "abnormal" protein, probably globulin, should not readily enter the urine. The evidence indicates that proteins are excreted on the basis of molecular size, configuration and electrical charge, rather than on the basis of some intrinsic abnormality of composition, suggesting mechanical filtration from the plasma as the mode of excretion.

Certainly, there is much in favor of the belief that urinary proteins are derived from plasma. It has long been known that proteins in plasma and urine are coagulated and precipitated in the same manner.<sup>28</sup> More recently it has been found that precipitated protein fractions from the plasma and urine of a patient with nephrosis are identical so far as the optical rotation, specific refraction, racemization, osmotic pressure, nitrogen distribution and immunologic properties are concerned.<sup>22, 23, 29-32</sup> Even though these studies have not been made upon pure fractions they establish beyond reasonable doubt the source of urinary protein. Hence it may be concluded that urinary proteins are derived from plasma by a filtration mechanism.

The obvious site of protein filtration is the glomerulus, where continuous ultrafiltration of plasma water and solutes has been shown to occur normally.<sup>33, 34</sup> The presence of precipitated protein in the glomeruli of patients with proteinuria lends further credibility to this view. There is nothing to suggest that tubular protein excretion plays a role, but it is possible that altered reabsorption may be important.

Normally, protein does not appear in the urine in concentrations greater than 90 mg per 100 cc or in amounts exceeding 150 mg per day.<sup>35</sup> Thus, there is either insignificant passage of protein through the walls of the glomerular capillaries or almost complete removal of protein from the filtrate by tubular cellular activity. Samples of glomerular filtrate have been obtained in mammals by micropipette<sup>34</sup> and little or no protein detected, but the best methods available for the determination of proteins in such small volumes fail to show concentrations below 25 mg per 100 cc.<sup>36</sup> Hence, it is possible that the human glomerulus produces a filtrate containing 200 mg per 100 cc and that, assuming a normal daily filtration volume of 175 liters, 35 gm of protein may be made available in this way for possible loss in the urine. If these considerations are correct, a considerable proteinuria

might develop as a result of a failure of tubular protein reabsorption. Even then, however, insufficient protein would be excreted to account for the huge losses — as much as 60 gm per day<sup>37, 38</sup> — occasionally observed during the nephrotic syndrome. When it is remembered that, in addition, the plasma protein concentration is greatly reduced, with a lower filtrate concentration in consequence, and that the filtration rate may be less than normal, it becomes obvious that tubular dysfunction cannot be the sole basis for proteinuria. Increased filtration of protein must occur, apparently as a result of an alteration in the glomerular capillary walls rather than in the nature of plasma proteins. It is possible, of course, that reduced tubular reabsorption plays a contributory role, but the evidence presented below indicates enhanced rather than diminished protein reabsorption. Thus, regardless of etiology, proteinuria in the nephrotic syndrome is attributable to defective glomerular activity.

#### ALTERATIONS IN RENAL STRUCTURE AND FUNCTION

The renal structural alterations associated with the nephrotic syndrome are exceedingly diverse and often obscure. There is a paucity of pathological material owing to the fact that most patients recover from the disease or progress into some more advanced phase before death. Cases have been reported singly or in very small groups.<sup>39-43</sup> In such studies no characteristic lesion has been marked out, and in a certain proportion of cases no renal disease has been found. As a rule, however, glomerular and tubular lesions are present.

The glomerulus is the logical center of attraction, but the search for lesions is often disappointing. According to Bell<sup>6</sup> and others,<sup>44</sup> the basement membrane is the most important component of the glomerular capillary wall since the endothelium is delicate, sparse and possibly not intact. There is a small amount of connective tissue between capillary loops forming a mesentery-like supporting structure often referred to as the "mesangium."<sup>44, 45</sup> A thin epithelial membrane covers the entire filtering surface, reaching in between capillary loops and dipping down into the spaces between the lobules. Thickening of the basement membrane, proliferation of the intercapillary connective tissue and piling up of endothelial cells (though the last is denied by MacCallum<sup>46</sup>) occur characteristically in chronic diffuse glomerulonephritis. During the nephrotic phase these changes are not extensive. In only a few glomeruli has the process resulted in hyalinization and obliteration.<sup>5</sup> Thus, the total area of the filtration bed is not greatly altered, although it is evident that the changes in the nature of the filter might be expected to result in a somewhat different filtrate composition. Similarly, in other disorders giving rise to the nephrotic syndrome glomerular lesions that do not appear to encroach seriously upon the filtering area are found. In amyloid disease,

there is a deposition of complex protein, possibly related in some manner to antibody production,<sup>47</sup> in the pericapillary spaces between the basement membrane and endothelium.<sup>48</sup> With progression, of course, compression of capillaries and obstruction to blood flow may lead to glomerular destruction. The renal disorder associated primarily with prolonged diabetes mellitus, intercapillary glomerulosclerosis,<sup>49-52</sup> is characterized by the appearance of nodular masses believed to arise from sclerosis and hyalinization of intercapillary connective tissue. The capillaries are pushed apart, and the glomeruli may be strikingly deformed by this material. In contrast, the glomeruli in kidneys of patients, usually young children, dying during the course of lipid nephrosis present few or no alterations. There may be some increase in the nuclear content of a few glomeruli, and adhesions between the tuft and Bowman's capsule may be demonstrable in some areas.<sup>53, 54-56</sup> Bell<sup>5</sup> has reported diffuse thickening of the basement membranes in a few cases and claims to have found "pores" through which protein might escape into the urine. It is certain that there are no obvious glomerular lesions in many cases of the disorder. This is also true of the few cases of the nephrotic syndrome that have developed after thrombosis of the renal vein.<sup>57, 58</sup> The absence of glomerular lesions does not preclude capillary injury and increased protein filtration; however, since Walker and Oliver<sup>1</sup> found that protein appeared profusely in the filtrate after minor trauma to capillaries without visible injury.

The tubular pathology is almost always outstanding, after the disorder is well established.<sup>59</sup> Fatty and colloid substances appear as droplets or vacuoles in the tubule cells, particularly in the proximal segment. Nearly all the cells in this part of the nephron may be filled to bursting with brightly refractile fat.<sup>67</sup> The deposit is distributed irregularly, and groups of grossly swollen cells bulging out through the basement membrane may give rise to contortion and kinking of the tubules. In many places the nuclei are pyknotic, and there may be necrosis with desquamation of portions of the tubular epithelium. As a result of these changes, which occur in every type of the nephrotic syndrome, the kidneys become large, pale and rather yellowish and firm but not fibrotic. A few microscopic scars may be found scattered through the parenchyma, to a greater extent perhaps in the nephritic and amyloid forms, but rarely sufficient to cause grossly detectable fibrosis or contraction.

The source of the cellular inclusions typical of the nephrotic kidney is not settled. They were at first considered a result of cellular degeneration. The demonstration that the lipid content of the kidneys is increased<sup>68</sup> appears to indicate, however, that intracellular fat is not unmasked by a change in physical state (fat phanerosis) but is deposited from without. The nature of the hyaline colloidal mate-

rial has been elucidated by Gérard and Cordier,<sup>69</sup> Smetana and Johnson<sup>70</sup> and others who have approached the problem through comparative physiology. In the salamander a certain number of nephrons communicate directly with the peritoneal cavity, whereas others do not ("open" as opposed to "closed" nephrons). After intraperitoneal injection of solutions of various proteins bound to dyes and of nephrotic serums, brightly stained droplets of protein and doubly refractile bodies are found only in cells throughout the length of the open nephrons, none appear in cells of the closed nephrons. These findings support the conclusion that the reabsorption of protein and lipids from the glomerular filtrate by the tubules might account for the tubular pathology of the nephrotic syndrome. A similar phenomenon has been observed in mammals.<sup>71, 72</sup> Administration of protein-dye compounds to rats with proteinuria results in the appearance of deeply stained globules in the cells of the proximal segment. In the absence of proteinuria these substances do not pass into the urine, and tubular lesions do not develop.

Such data must be used cautiously in the interpretation of the tubular changes in nephrosis in man. There are excellent reasons for the belief that there is protein filtration, and it certainly seems probable that reabsorption of protein from the filtrate may induce certain alterations in cell structure. It is unknown, however, whether these changes are based upon overactivity of normally active reabsorptive mechanisms. Oliver<sup>73</sup> objects to the notion that the large, obviously destructive deposits of fat result from such overactivity because the deposits are irregularly dispersed. There is no information available regarding the distribution of reabsorbed protein in the tubular cells or its relation to fat infiltration. Fat tends to accumulate in injured cells,<sup>74</sup> and it is possible that a similar process occurs in the kidney after injury by excessive protein reabsorption. In the nephrotic syndrome the blood contains a high concentration of lipids in the colloidal state apparently forming large complexes with various globulins.<sup>75</sup> It is probable that such compounds are not readily filtered even when albumin traverses the glomerular membrane with ease. In line with this view is the low concentration of lipids in the urine, despite marked lipidemia.<sup>76-78</sup> That which appears in the urine seems chiefly to be contained within the desquamated tubular cells comprising the numerous urinary casts. Centrifugation of the urine removes most of the detectable lipids, apparently by removing this cellular debris. Hence it is not unlikely that fats and cholesterol enter the tubule cells from the blood rather than from the glomerular filtrate. Further study is necessary to answer this question.

The urine is often highly concentrated, containing cellular elements or casts of various kinds in great numbers. Erythrocytes, leukocytes and epithelial

cells may appear abundantly in the urine. Hematuria has been considered exceptional, but repeated examinations of the urine disclose showers of red cells from time to time in nearly every patient. Even in lipoid nephrosis, in which the absence of blood from the urine is regarded as a *sine qua non*, red cells are occasionally found. Casts are composed of coagulated protein, alone, or binding a heterogeneous mixture of cells and cellular material. In view of the high concentration of protein in nephrotic urine it is rather surprising that cast formation is not more impressive than it is. High concentrations of salts and urea have a dispersive influence upon proteins in solution, whereas reduction of the reaction of the glomerular filtrate during its passage down the tubule tends to favor precipitation.<sup>57</sup> There is some evidence that the introduction of a protein precipitant by tubule cells is necessary to disrupt these balancing influences, and to bring about protein coagulation.<sup>57</sup> Whether cast formation is restrained in the nephrotic syndrome by adequate concentrations of various dispersive solutes or by insufficient precipitant is unknown.

On the whole, kidney function appears to be excellent. Many writers have stressed the normality of concentrating power, phenolsulfonephthalein excretion and urea clearance and the absence of nitrogen retention, acidosis and other evidences of renal insufficiency.<sup>2, 55, 56</sup> Considering the state of the kidney it is not surprising that this should be so. Although glomerular lesions are demonstrable, there is little or no destruction of glomeruli. Hence filtration should not be greatly affected. The renal vascular system is relatively undisturbed, and blood continues to perfuse renal tissue normally. Although the tubular lesions may be striking, little loss of nephrons is incurred. Renal functional alterations are demonstrable only by more refined techniques in most cases, particularly in lipoid nephrosis. Occasionally, however, the disturbance is more profound. Indeed, evidence of renal insufficiency develops sooner or later in most cases of the nephrotic syndrome in which progressive renal damage occurs, as in the course of chronic diffuse glomerulonephritis, intercapillary glomerulosclerosis and amyloidosis.

The glomerular filtration rate is usually reduced moderately, to values as low as 50 per cent of normal in many patients with chronic renal disease.<sup>67-69</sup> In children with lipoid nephrosis, on the other hand, the filtration rate may be increased markedly.<sup>70-72</sup> The urea clearance tends to follow filtration rate and to present similar decrements and increments. Although the possible causes of diminished filtration are obvious, it is difficult to explain the augmentation in children. Such a change may be the result of increased effective filtration pressure secondary to a vasomotor adjustment or to the fall in plasma oncotic pressure due to hypoproteinemia.

In the few cases studied thus far renal blood flow has been found within normal limits or slightly decreased.<sup>67-69</sup> In lipoid nephrosis elevations in blood flow have been reported.<sup>72, 73</sup> What these changes may imply regarding vasomotor activity within the kidney we cannot at present state with any certainty.

Tubular function is usually unaffected. Various measurements, such as those by glucose, Diodrast and para-aminohippurate Tm, tend to be normal despite the reduction in filtration.<sup>69</sup> Thus, the stream of urine may flow more slowly down the tubule, prolonging its contact with active reabsorptive cells and providing an improved opportunity for reabsorption of water and solutes. This phenomenon of glomerulotubular imbalance may account for continued normality of concentrating power and for occasional fixation of urinary specific gravity at a high level. It is possible, too, that urea reabsorption may be enhanced in this manner to give rise to the modest elevation in blood urea sometimes observed. Certainly, the tubule cells appear to acquit themselves well. Not only can they reabsorb water and electrolytes normally or even in excess but also they are capable of adequate excretion of hydrogen ion and of ammonia synthesis.

Renal functional and anatomic abnormalities are thus demonstrable in every case of the nephrotic syndrome. They vary considerably in kind and degree, but are never so severe as to suggest extensive damage and loss of tissue. These processes are characteristically reversible. Every trace of the disorder may disappear, and the kidneys return to normal in many patients, even after a prolonged illness. In others, however, parenchymal damage may finally ensue with the development of renal insufficiency as nephrons disappear and the glomerular filtration bed shrinks. In this process the nephrotic syndrome clears.<sup>55, 56</sup> Proteinuria is less marked and may ultimately cease altogether, apparently as a result of the obliteration of defective glomeruli and the diminution in the available filtration surface through which protein may escape from the blood. As protein loss diminishes, the plasma protein concentration rises and peripheral edema regresses.

#### CASE 34071

##### PRESENTATION OF CASE

A fifty-seven-year-old man entered the hospital because of a lump in the right upper quadrant.

The patient's attention was first called to his abdomen three weeks prior to admission when he had an acute pain in the region of the umbilicus while attempting to lift a plank. The pain persisted for two hours and then disappeared completely; it was not accompanied by nausea, vomiting or other gastrointestinal symptoms. At that time he noted the mass, which was tender and which in the following three weeks grew slightly larger and moved up and to the right. Following the discovery of the mass he limited his food intake, and his bowel movements became somewhat more scanty, having previously been regular. The only change noted in the character of the stools was that they were perhaps somewhat lighter in color. An estimated 10 to 15 pounds of weight had been lost during the present illness.

The patient had been addicted to morphine for thirty-seven years, a habit initiated by taking the drug for several attacks of right-lower-quadrant pain diagnosed at the time as chronic appendicitis. Six major and numerous minor attempts were unsuccessful in breaking the habit.

Physical examination showed a slender, rather nervous man. There were numerous injection scars on the arms and thighs. Examination of the heart and lungs revealed only emphysema. The abdomen was flat and soft throughout. In the right upper quadrant there was an irregular, firm, movable, tender mass, 8 by 6 cm. in diameter, which appeared to be attached posteriorly but was thought not to be connected to the liver.

The temperature, pulse and respirations were normal. The blood pressure was 160 systolic, 85 diastolic.

Examination of the blood showed a hemoglobin of 13.5 gm. and a white-cell count of 10,400. The urine was normal. Two stool specimens were guaiac

negative. The nonprotein nitrogen was 31 mg. per 100 cc., the total protein 8.18 gm., with 4.53 gm. of albumin and 3.65 gm. of globulin, the phosphorus 3.5 mg. and the phosphatase 4.9 units. The van den Bergh reaction was normal, and the cephalin flocculation test +++ in twenty-four and forty-eight hours.

An x-ray film of the chest disclosed findings consistent with emphysema, a barium enema showed no evidence of disease intrinsic to the large bowel and no evidence of external compression, an intravenous pyelogram demonstrated no evidence of disease of the urinary tract, a gastrointestinal series was not completely satisfactory but no abnormalities were made out, and a cholecystogram showed no definite evidence of a gall-bladder shadow. On one film the right kidney and its pedicle were seen to be outlined more clearly than usual.

On the tenth hospital day an operation was performed.

##### DIFFERENTIAL DIAGNOSIS

DR. RICHARD H. SWEET: As we progress with this history the real decision that we have to make is whether the tumor, which was very obvious in the patient's abdomen, had anything to do with the trauma that is described, because the record mentions that the patient's attention was first called to the abdomen when he had acute pain in the region of the umbilicus while attempting to lift a plank. It is a very short history. I do not know whether he was a good plank lifter or not, but people accustomed to lifting heavy weight know how to do it, so that they do not rupture a deep epigastric artery and cause abdominal-wall tumors of traumatic origin. I am rather inclined to discount the trauma. At any rate he felt the pain and this pain was short-lived — lasting only two hours in duration and disappearing completely — and we assume that it never came back.

"Following the discovery of the mass he limited his food intake." That statement makes no sense, since it does not reveal why he limited the food intake. He had no nausea or vomiting, and was supposed to feel well. Limitation of food intake is unusual simply because a patient feels something in the abdomen. Perhaps his doctor had something to do with it.

The fact that the patient was a morphine addict is important, because I believe that it makes the history completely unreliable. I have never seen a morphine addict who could tell a straight story about anything, especially about his own symptoms. That discourages me. I do not consider this history worth anything in the making of a correct diagnosis.

I should say that the laboratory findings were within the normal range. I imagine that liver disease was looked for, and I assume that there was no evidence of it.

I also assume that the gastrointestinal series was not repeated even though it was not satisfactory. I suppose that the cholecystogram revealed a shadow, but the examiners were not sure of it, it was not definite. That is the only thing about the x-ray examination that interests me.

On one film the right kidney and its pedicle were seen to be outlined more clearly than usual. I do not understand what that means. Did the patient have some retroperitoneal gas or some air outlining the kidney and its pedicle? That is unusual to see, is it not, Dr. Wyman?

DR. STANLEY M. WYMAN: Yes. The chest is clear but shows emphysema. The patient did have two gastrointestinal examinations. They show a normal-appearing stomach and duodenal bulb and loop. There is a little calcification in the left upper quadrant, which probably lies in the splenic vessels. On one of these films that cannot be seen clearly, there is a somewhat irregular pattern of the esophagus, which makes me raise the question of possible varices. I cannot make a definite statement because the film is not sufficiently good.

DR. SWEET: You do not see any definite mass?

DR. WYMAN: The right colon is pushed down somewhat. That may be a large liver, or possibly a mass that cannot be outlined.

DR. SWEET: I think it is stated somewhere that the mass was attached posteriorly and that it was not connected to the liver. That is an important observation, if we are going to decide what this mass might be. The statement may be correct, it may not be. I know that I can make that error myself. I have occasionally seen an enormous hydrops of the gall bladder in which the fundus of the gall bladder felt very much like an ovarian cyst lying in the right lower quadrant of the abdomen. The problem resolves itself into a very simple matter of deciding what the abdominal tumor was. Presumably it was of short duration and was easily felt by the physicians in attendance. It was a hard, irregular, movable mass not connected with the liver but attached posteriorly. The gall bladder is usually smooth and not irregular, unless it is involved in carcinoma. It is almost always attached to the liver. A carcinoma of the duodenum is excluded by the x-ray findings, as is carcinoma of the pancreas. A renal-cell carcinoma would also have shown some abnormality of the kidney shadow in the intravenous pyelogram. Carcinoma or other tumor of the hepatic flexure ought to be thought of, but there again the x-ray film ought to exclude it. That brings us down to the assumption that this tumor was retroperitoneal, one of those unusual mesenteric cysts, or something of that sort. But it was hard and irregular, so that we might on that basis exclude such a diagnosis. I should like to mention lymphoma, but the retroperitoneal lymphomas that we see are usually farther over to the

midline, almost always fairly fixed in the posterior aspect of the abdomen.

I should like to return again to the question of trauma, because I should at least mention the possibility that there was a hematoma from a ruptured vessel from lifting the plank. Trauma of that sort is most apt to cause rupture of the deep epigastric artery, and then of course the tumor lies in the rectus sheath. In that case the patient has cramping pain, which does not disappear in two hours. It brings the patient into the hospital. An emergency operation is often performed because the pain is so intense, although the diagnosis can be made ahead of time.

Having mentioned most of the possibilities that I can think of, I am inclined to agree that this was a surgical case and that the patient should have been operated on, but I think it is very premature to attempt to make a diagnosis.

DR. BENJAMIN CASTLEMAN: Does anyone wish to offer to make a more definite diagnosis?

DR. WYMAN: I wonder if Dr. Sweet would consider the possibility of hepatoma very early.

DR. SWEET: Yes, I intended to speak of it. Tumor of the liver, although the mass is not connected with the liver on physical examination, should be mentioned — a tumor arising in the liver on a pedicle. I have actually seen such a tumor.

DR. WYMAN: My reason for mentioning it is that if the esophageal irregularity pointed to varices, that diagnosis might occur.

DR. SWEET: I excluded that possibility because the gastrointestinal tract was normal.

#### CLINICAL DIAGNOSIS

Carcinoma of gall bladder?  
Carcinoma of bile ducts?

DR. SWEET'S REPLY

Morphinism

#### ANATOMICAL REPLY

Subacute and chronic perforation  
Cholelithiasis

#### PATHOLOGICAL REPLY

DR. THOMAS GREEN: To reconfirm course, by the history I have the ad of peritoneoscopy body, which is included in the report of the Benedict as shown in the retroperitoneal area, I am sure I might say that the

ward this mass was well below the liver edge and did not seem to move with the liver, although he did not have, as I remember it, marked excursion of the liver on inspiration and expiration

At operation we explored the right upper quadrant, and on opening the abdomen we found a large mass covered with omentum extending down the right side of the abdomen. It was found to be attached to the transverse colon, and when it was freed, it became obvious that it was an acutely and chronically inflamed gall bladder, the thickened wall extending to the level of the umbilicus. When we first felt it, it was so hard that we thought that it was carcinoma. On freeing it from the omentum, we broke into it, and a large amount of yellow pus escaped. It was necessary to free it from the transverse colon with sharp dissection, and we found numerous stones, one of which — a large one — was impacted in the ampulla of the gall bladder at the beginning of the cystic duct. In retrospect, putting the picture together, we thought that the patient had an inflamed gall bladder completely masked by the morphine addiction, probably, as he lifted the plank the gall bladder ruptured and he developed a localized peritonitis, which fortunately for him he was able to tolerate well. The wall of the gall bladder in one place was 2 cm thick. After we removed it we asked the laboratory to do a frozen section, and there was no evidence of carcinoma.

DR CASTLEMAN There was a piece of tissue removed from outside the gall bladder that showed a gallstone surrounded by foreign-body reaction, so that we have proof that the gall bladder had perforated, probably after the patient lifted the plank three weeks previously. The wall showed a subacute and chronic inflammatory reaction but no carcinoma.

## CASE 34072

### PRESENTATION OF CASE

A forty-one-year-old gasoline-station operator entered the hospital complaining of boring epigastric pain.

Five years prior to admission the patient first experienced pain in the epigastrium, occurring after meals and relieved by food or alkali. A Graham test two years before admission failed to visualize the gall bladder. Following this, an operation was done, and the gall bladder was not found. An appendectomy was performed. The pain reappeared after a year's alleviation following operation. He had been eating "anything and everything."

Physical examination of the chest and abdomen was negative, there was a healed scar over the right rectus muscle.

The blood pressure was 130 systolic, 85 diastolic

Examination of the blood disclosed a hemoglobin of 15.3 gm and a white-cell count of 10,900. Urinalysis gave a specific gravity of 1.012, and was negative for sugar, albumin and diacetic acid, rare white cells and epithelial cells were seen in the urinary sediment. A gastrointestinal series showed enlargement of the gastric rugal folds. The duodenal bulb was constantly deformed and showed pooling of barium in the midportion, with a surrounding area of rarefaction, consistent with edema about a crater.

On the fifth hospital day a subtotal gastrectomy, with a gastrojejunostomy, was done. Two days later the patient's condition was "alarming," with low blood pressure, a thin rapid pulse, peripheral vascular collapse and cyanosis. The temperature was 102°F orally. The chest was clear. The abdomen was silent and only slightly distended. Penicillin and streptomycin were started. Following this, he passed very little urine, and the nonprotein nitrogen rose to 110 mg per 100 cc on the third postoperative day. Because of tenderness and spasticity in the right upper quadrant an incision was made and about 1000 cc of "grossly uninfected bile" was drained. On the fifth day, following the original operation, the temperature remained elevated, and the nonprotein nitrogen rose to 165 mg per 100 cc. The serum amylase was reported as 100 units, and atelectatic areas were visualized at the right base by x-ray examination. The patient expired on the eighth day following the original operation.

The fluid exchange during and after the operation was as follows:

	INTAKE		OUTPUT	
	INTRAVENOUS cc	ORAL cc	URINE cc	LEVINE TUBE cc
Day of operation				
Transfusion	1000			
5 per cent dextrose in water	1500			
5 per cent dextrose in physiologic saline solution	1000	0	Unknown	0
First day				
5 per cent dextrose in water	1200			
10 per cent Amigen	1000	360	120	1000

Eighth day:				
5 per cent dextrose in physiologic saline solution	500			
5 per cent dextrose in water	2700	1150	1580	690

## DIFFERENTIAL DIAGNOSIS

DR. CHARLES L. SHORT: May we see the x-ray films?

DR. STANLEY M. WYMAN: There is a small hiatal hernia seen on all films. There is slight prominence of the gastric rugae. The duodenal cap is strikingly deformed, constantly throughout two examinations. The small pool of barium seen proximally in the cap may represent a crater or possibly barium caught between folds. The duodenal loop is normal in size and contour. There is no evidence of excretion of the gall-bladder dye on one examination. The post-operative film of the chest taken with a portable apparatus shows atelectasis at both bases, but clear lung fields otherwise.

DR. SHORT: Would you say that a definite ulcer crater was demonstrated?

DR. WYMAN: In going back over the films, I am not entirely convinced that it is. I think that it might perhaps more readily be interpreted as barium between folds for the reason that the contour appears to change and a crater would remain constant.

DR. SHORT: Do you see any air or barium in the hilum?

DR. WYMAN: No, I do not.

DR. SHORT: Do you think that these defects could be caused by adhesions outside the duodenum, such as pericholecystitis?

DR. WYMAN: They are more consistent with a deformed cap from an old duodenal ulcer.

DR. SHORT: We have a reasonably certain x-ray diagnosis, then, of an active duodenal ulcer, although the roentgenologist is not quite willing to say that the picture is absolutely diagnostic. The patient's history seems typical of this condition, including a year of remission of symptoms. Perhaps a different history given two years before directed attention toward the gall bladder, and at that time a positive Grabam test was obtained.

The next statement is a surprising one — that the gall bladder was not found at operation. I can think of three possible explanations for this, although there may be more. The patient may have had congenital absence of the gall bladder. This is a rare condition, but cases have been recorded.

The second is that the gall bladder occupied an anomalous position, perhaps embedded deep in the liver, or was covered by a congenital band. The most likely possibility, I think, is that identification of the gall bladder was difficult on account of adhesions in that neighborhood. In view of the x-ray findings the source of the adhesions may well have been a healed perforation of a duodenal ulcer, although we must still bear in mind the possibility that the patient had cholecystitis. Physical examination is not helpful, and the urinalysis gives no hint of underlying renal disease. We can assume that the preoperative diagnosis was duodenal ulcer and that the indications for operation were that the patient was unable or unlikely to follow a medical regime. Since a gastric resection was performed, fairly good evidence of duodenal ulcer must have been found at operation. I shall be interested in hearing later more details of the findings, especially regarding the presence or absence of the gall bladder and of adhesions in that area.

Two days after operation the patient's condition suddenly became worse, with the development of fever and a state of shock. Examination of the abdomen revealed the development of at least a localized peritonitis. In view of the drainage of large amounts of bile two days later, it seems to me that the conclusion is inevitable that the patient had peritonitis that had arisen at the duodenal stump, either from leakage or from actual rupture. A more remote possibility is that the patient actually had gallstones and that one had ruptured through the gall bladder or common duct with the development of bile peritonitis. Acute pancreatitis is another possibility. Certainly it would be a rare complication of an operation in this area. I do not see how one could make that diagnosis from the evidence at hand. I do not believe that the elevated serum amylase is significant in view of the degree of renal failure. If we accept any of the diagnoses I have mentioned, the absence of pain at the time of this catastrophe would be unusual. In view of the history and x-ray films and the findings at operation, I shall assume that the patient did not have cholecystitis and am willing to eliminate that diagnosis.

We can only speculate regarding the cause of the duodenal leakage. From the figures that we are given on fluid exchange I do not believe that we can say that the patient was given too much water and salt immediately after operation, with the consequent development of edema and obstruction in the region of the stoma. Following the development of peritonitis the patient's course was marked by anuria succeeded by oliguria and the gradual resumption of a respectable urinary output. Except for the fourth postoperative day, when drainage was done, he maintained a positive fluid balance. The nonprotein nitrogen rose rapidly, however,

reaching 165 mg per 100 cc by the fifth post-operative day. The amount of fluid lost through external drainage is not recorded after the first day, and he undoubtedly continued to lose large amounts of fluid, electrolytes and protein through exudation into the peritoneal cavity. It is possible that the azotemia was due to the extrarenal causes I have mentioned, but more likely to some form of severe renal damage. I am referring to lower-nephron nephrosis, the common etiologic factors of which are shock, intravascular hemolysis and sulfonamide toxicity. He certainly went through a period of shock, intravascular hemolysis is possible since he received 1000 cc of blood, but we have no record of sulfonamide administration. Further data on the blood chemistry would be of interest but not diagnostic. The urinary findings, especially his ability to concentrate, would also be helpful. He evidently did not develop obvious edema, and we have no record of a blood-pressure rise before death.

It is hard to decide whether he died from sepsis or renal failure—probably a combination of the two. It is possible that he might have pulled through in the absence of peritonitis since he had an adequate urinary output in the last three days. It is difficult from the data at hand and without seeing the patient to comment on the fluid therapy that was employed. The amount of salt and fluid given the patient following the development of anuria seems contrary to the accepted principles of tiding over a patient with lower-nephron nephrosis with minimal amounts of both until renal function is resumed. But this patient in view of losses through drainage and exudation seemed to need more fluid and salt than the 500 to 1000 cc, including 300 cc of physiologic saline solution, which is usually prescribed by those who have studied this type of renal damage. However, I think that therapy may have been a little too enthusiastic and that some edema of the lung and other tissues was found at autopsy. In conclusion, I shall offer the following diagnoses: duodenal ulcer, bile peritonitis secondary to leakage from the duodenal stump and lower-nephron nephrosis.

DR TRACY B MALLORY: Dr Welch, will you discuss the operative findings?

DR CLAUDE E WELCH: The treatment that the patient had before he came to the hospital represented a long series of medical attempts with alkalies and bland diet, with never any relief of

symptoms, so that he was very unhappy about the situation and something was needed surgically. We believed that there was a certain amount of difficulty in making a clear-cut diagnosis, especially in view of the previous surgical findings. Therefore, I decided to do a laparotomy with a gastric resection, if he turned out to have an ulcer, rather than a transthoracic vagotomy. He turned out to have a large duodenal ulcer, one that was nonresectable. In other words, it involved the whole first and second portions of the duodenum, running down to the common duct. Consequently, I elected to do a procedure that was originally described by Finsterer<sup>1</sup> and later by Wilmanns<sup>2</sup> and others, in which the stomach is transected proximal to the pylorus, the entire mucous membrane of the pyloric segment removed and the muscularis of the stomach closed. One of the difficulties of this type of operation is the danger of leakage from the gastric stump, which does not heal so well as the duodenum. To date we have had no fatality from this course, and the operation has been carried out in 30 or 40 cases. The blood supply seemed to be extraordinarily good at the time, and we were successful in getting an excellent closure.

The postoperative course was of interest, and Dr Short has analyzed it very accurately. A great deal of blood chemical study was done but not recorded in the printed summary. It became obvious at the end of sixty hours that the patient was not doing well. There was a lengthy discussion regarding whether to do an exploratory incision at that time to discover the cause of the trouble. An exploration was carried out, and bile peritonitis, presumably from a leak of the gastric stump, was found. Thereafter fluids were given in accordance with the blood chemical findings. The chloride was almost constantly low, which explains the fact that he received a rather high intake of chlorides.

DR BENJAMIN CASTLEMAN: What about the gall bladder?

DR WELCH: I could not find it at the time of operation.

DR SHORT: If the diagnosis of lower-nephron nephrosis is correct, the low chloride might have been explained on the basis of increased plasma volume.

DR WELCH: A tremendous amount of chloride was being lost through the abdominal drainage, it could not be accurately estimated.

DR JACOB LERMAN A certain amount of Amigen sometimes elevates the nitrogen faster than it can be excreted in the urine. It may be just a temporary situation.

DR MALLORY The patient had a definite oliguria that lasted four days, an output below 500 cc. on each of these days, and this figure is the minimum output that will clear nitrogenous waste products.

#### CLINICAL DIAGNOSES

Bile peritonitis  
(Duodenal ulcer)

#### DR. SHORT'S DIAGNOSES

Duodenal ulcer  
Bile peritonitis, secondary to leakage from duodenal stump  
Lower-nephron nephrosis

#### ANATOMICAL DIAGNOSES

Duodenal ulcer, chronic  
Operative wound, gastric resection and gastroenterostomy  
Perforation of pyloric stump  
Peritonitis, generalized, acute, with fat necrosis  
Lower-nephron nephrosis, healing  
Congenital anomaly — absence of gall bladder

#### PATHOLOGICAL DISCUSSION

DR. MALLORY Autopsy showed, as was expected, a perforation of the stump of the gastrectomy. There was an old scarred duodenal ulcer. There was no gall bladder. There was a slight diffuse peritonitis accompanied by many foci of fat necrosis throughout the peritoneal cavity, indicating that duodenal contents had made their way around through the gastroenterostomy and the perforation in the pyloric stump.

The kidneys were significantly enlarged, the combined weight being 450 gm. Microscopically they were interesting to me because they showed a subsiding but definite lower-nephron nephrosis as Dr. Short predicted. In these cases the tubules are usually rather massively blocked with hemoglobinuric casts. In this case only traces were left. On the other hand there were well marked degenerative changes in the epithelial cells of the lower segments of the nephron. There was the usual interstitial inflammation between the straight tubules, most marked at the junction of the cortex and medulla, and there were some of the interstitial granulomas that are frequently seen from the fourth to the fifth day in lower-nephron nephrosis. There was also a definite degree of cloudy swelling in the proximal tubules, which I think is not a characteristic part of the picture although there is some difference of opinion about that. So far as the kidneys were concerned, I believe that the patient could have survived. He had gone through the acute stage and had re-established fairly adequate urinary output, and the histologic picture in the kidney corresponds with that very closely. This was evidently a healing lesion.

DR. SHORT Were the lungs edematous?

DR. MALLORY There was only slight pulmonary edema. There was nearly 2 liters of fluid in the abdomen.

A PHYSICIAN Did the fluid contain much bile?

DR. MALLORY At the time of autopsy it was not so darkly bile stained as the fluid previously drained.

DR. SHORT From the autopsy findings parenteral fluid and salt were certainly not given in excess.

## BLUE CROSS

MUCH has been said and a great deal has been written during the past year about Blue Cross plans and their difficulties. In view of certain doubts and confusions that have arisen, it seems not only opportune but also most fitting that a careful analysis be made of a service that now makes available hospital care for almost thirty million of the American population.

It is essential to have in mind the purpose of the founding fathers of Blue Cross. This may be summarized as an effort to provide financial protection against the hazards of unpredictable illness, and the plans have been exceedingly helpful to their subscribers in making this protection possible through the years of Blue Cross existence. Until caught in the spiral of inflation, the plans have been helpful

to hospitals by guaranteeing reimbursement, with the advantage of an assured source of income, which has made budgetary planning, in a degree, easier and more secure. The importance of this factor can be better appreciated when one realizes that from 40 to 60 per cent of persons hospitalized in Massachusetts are Blue Cross subscribers. In view of this fact, Blue Cross must justifiably be considered a valuable voluntary instrument for protection against all, or part, of the hospital bill.

Varying methods of reimbursement to hospitals are in vogue throughout the country. Some are on the basis of established hospital charges, some on costs, and others in accordance with a previously agreed rate. Last June there was adopted in Massachusetts what is termed an all-inclusive plan—namely the furnishing to the subscriber of almost his total hospital needs. In the face of the continuing increases in the cost of hospital operation, this change played its part in the development of the present unsatisfactory situation. This is explained by the fact that whereas the costs were increasing, both subscription rates to subscribers and reimbursements to hospitals were expected to remain fixed for a period of a year. Factors of influence in Massachusetts that add to Blue Cross financial difficulties are a high incidence of admissions and a longer average hospital stay than occurs under other Blue Cross plans, with a consequent serious drain on Blue Cross financial resources.

The public, the hospitals and the medical profession must all play their part in the preservation of Blue Cross. To do this calls for cold, keen and careful analysis. The fear of increasing Blue Cross subscription rates must not be exaggerated or over-emphasized, for the American public is conscious of increasing costs in every line of endeavor and has shown its willingness to pay for what it receives. The zeal for maximum enrollment of subscribers on the part of those charged with this responsibility must not overshadow actuarial safety and sound financial management. Through it all, thinking and planning must be along a specific line—namely, the best interests of the public, which, after all, pays the bills. In exercising this concern and interest, the solvency of both the hospital and Blue Cross must be protected.

It is not too much to ask on behalf of the hospitals that Blue Cross subscribers do not add materially to their financial burdens. In the interests of mutual interdependence, it must be remembered that it is vital to the success of Blue Cross plans that hospitals remain financially sound, and it is not wise, when plans for the provision of voluntary care are extended, that either Blue Cross or hospitals should sustain financial losses. In the long run this must spell insolvency for one or the other, or both. If Blue Cross is to sell good hospital care, hospitals must be adequately compensated for furnishing that care. We cannot, therefore, escape the basic principle that the consumer, for whom the plan is provided, must pay an adequate premium or assume some portion of the risk that makes possible the service that he receives.

In conclusion, although it must be confessed that all is not well, it must also be realized that the patient (in this instance, Blue Cross) is not beyond cure and will be restored to health and usefulness if the public, the Blue Cross itself, the hospitals and the medical profession all do their part. If Blue Cross is to continue, as it should and *must*, the hospitals must support it staunchly, and those responsible for Blue Cross policy and management must be ever mindful that hospitals cannot endure without adequate reimbursement for the services that they render.

---

## HELP FOR THE EPILEPTIC PATIENT

ELSEWHERE in this issue of the *Journal* a survey by the American Epilepsy League entitled "Who Cares for the Epileptic?" deals with the persons with seizures (more than 90 per cent) who are treated — if treated at all — by physicians in private office or in clinic. The survey does not deal with two other important aspects of epilepsy: the care of the minority group in tax-supported hospitals, and the interest of the general public in this segment of the sick population.

The year 1948 marks the semicentennial of the opening of the Monson State Hospital for epileptic patients, near Palmer, Massachusetts. Dr. William N. Bullard, backed by the Massachusetts Medical Society, provided the impetus for this project. The

third colony in the United States specifically for the care of epileptic patients, Monson is probably second to none in the effective use of available resources. However, the facilities both in capacity and in personnel are sadly inadequate to meet the demand. Physicians, parents of patients or patients themselves look despairingly at the long line of applicants waiting for months or years before doors that seldom open. Neither the parents manacled to a defective, seizure-ridden and perhaps unmanageable child nor the adult patients who are sound of muscle and mind but cannot keep a job because of uncontrolled convulsions are in a position to complain of the sort of physical and medical care that costs a total of less than \$1.50 a day, including less than 40 cents a day for food. (In sharp contrast, the amount paid by taxpayers for the hospitalization of epileptic veterans is approximately ten times greater.)

The obvious solution to the plight of the hundreds of waiting patients is more beds (in which there has been no increase at Monson for more than twenty years) with, of course, a larger budget both to maintain the beds and to provide wages high enough to attract personnel. However, the present yearly cost of institutionalized epileptic patients in Massachusetts is already in excess of a million dollars, and dispensers of public funds will want to know the causes for the present congestion and whether other alleviating measures might also be instituted.

The subject merits a broad and disinterested study, but two causes of congestion are immediately apparent. With bed space static, new patients cannot enter unless old ones leave. Thanks very largely to the development of the electroencephalograph and of more effective drugs in the last two decades, the control of seizures has been vastly improved. An increased turnover of institutionalized patients might be anticipated, but the present combined death and discharge rate of approximately 10 per cent is less than half the rate that obtained in the bromide period thirty years ago. Instead of developing a more rapidly moving stream of patients entering and leaving, epileptic colonies are becoming stagnant pools. Advanced medical care given to the hopelessly defective and a lack of social science

for the hopeful patients tend to block the exits of the institution. The lives of imbecile children with brains undeveloped or irreparably damaged, whose only hope is death, are prolonged through the conscientious use of prophylactic inoculations against childhood infections. Thanks to the sulfonamides and penicillin, pneumonia is no longer the friend of the aged to the extent that it once was. Tuberculosis, formerly a 10 or 12 per cent contributor to death in institutions, is under control at Monson. A recent survey by means of chest films disclosed less tuberculosis than in the outside population.

However, the decrease in exits because of death has been less in recent decades than the decline in the discharge of living (usually improved) patients. One reason may be the retention of the more able adult patients, which helps to keep down the cost of services. Doubtless a careful survey of patients would disclose a number whose seizures are under control and who might return to the family or the community and make way for patients more urgently in need of hospital care. Such a survey and resulting placements would require the professional help of social workers. At present the hospital staff and the 1400 patients have not a single social worker to help them in their multiplied social problems, although formerly Monson was adequately supplied — a circumstance that may account for the greater rate of discharge at one time. Doubtless each dollar spent in salary and adequate working conditions for competent social workers would save many dollars now lost through a stagnating pool of patients. A "total push" method of medical and social therapy would probably enlarge the outlets of the pool and permit the entrance of actively epileptic adult patients able to do the work of those discharged. During the past year, deaths numbered 54, and discharges 74. The total of 128 is approximately 10 per cent of the patients, which means residence for an average period of ten years, at a total cost per patient of at least \$5000, of which approximately \$250 is paid by the patient or his family.

However, the greatest long-range saving of money and release from the pressure of applicants should come from decreased need for institutionalization. As a money and health saver, prevention far out-

measures treatment, especially in epilepsy, in which a few capsules of medicine a day may mean the difference between social dependence and independence. Early diagnosis and institution of proper medical and social therapy for patients would prevent many a patient from ever entering Monson and becoming a public charge. Massachusetts has led the world in research, in drug therapy and in lay support of epileptic patients. In recognition of this fact, a National Veterans Epilepsy Center has been established at the Cushing Veterans Administration Hospital at Framingham. Establishment of a somewhat similar preventorium of chronic epilepsy and its sequelae near a center of medical influence for the short-term treatment, education or training of young persons of good intelligence would be a pioneer and profitable investment of public money. Contact with this group of patients, whose prognosis regarding both seizures and social usefulness is good, would increase the interest and the spirit of the medical, nursing and social-therapy staffs of Monson.

The second domain of importance for epilepsy and the most fundamental to the proper care of patients is the attitude of the general public. When the public realizes how much can be saved in dollars and in tears through medical research, through early and intelligent treatment of persons subject to seizures and through preventive measures intelligently applied (eugenics, better obstetrics, fewer childhood infections and fewer industrial, automobile and war injuries) enterprises now only dreams will quickly become facts. Experience has shown that public sentiment is changed only when groups of interested persons deadily in earnest get behind a program of enlightenment. This has happened for the epileptic patient in the organization of the American Epilepsy League, with an affiliated New England chapter with headquarters at 50 State Street, Boston. The New England Epilepsy League, which acts as a leaven in the otherwise unresponsive dough of public opinion, inspired the survey of Massachusetts doctors reported in this issue of the *Journal*, as well as a survey of all schools of higher education in the United States reported in the current issue of *Epilepsia*. It seeks to overcome prejudice among educators and employers and to aid phy-

sicians in their care of patients, whether private, clinic or institutional. It would lend its experience and knowledge to any broad-visioned, long-term plan for the prevention and better treatment of epilepsy, with consequent saving of both money and socially useful lives.

## THE NOLEN-MILES POUND LAW

ATTENTION is called to the communication by Dr. John Conlin, director of medical information and education of the Massachusetts Medical Society, which appears on the following page. It is of paramount interest to all physicians. Senate Bill 264 is pending before the General Court of the Commonwealth of Massachusetts. This legislation, entitled "An act to make available unclaimed and unredeemed animals impounded in animal pounds for scientific investigation, experiment or instruction" is of the utmost importance.

Medical schools and hospitals are facing a critical shortage of dogs and cats for experimental purposes. This is not a simple matter of fund raising or of passing financial difficulty. Animals are simply not available. It is incongruous that this situation should obtain while thousands of animals are destroyed annually in the public pounds. These animals, vagrants and strays, are condemned to death as a menace to the health of the community. How much better that some of them should have death deferred until under humane auspices they are used for studies contributing to the health and welfare of humanity and of animal pets!

A hearing on S. 264 will be conducted before the Committee on Legal Affairs at the Gardner Auditorium at the State House in Boston on Tuesday, February 24, at 10.30 a.m. It is a matter of the greatest importance that legislators be informed of the urgent and cogent reasons for the passage of this bill.

The Constitution of the Commonwealth, in Section II of Chapter V, states "Wisdom and knowledge, as well as virtue, diffused generally among the body of the people, being necessary for the preservation of their rights and liberties, and as these depend on spreading the opportunities and advantages of education in the various parts of the country, and

among the different orders of the people, it shall be the duty of legislatures and magistrates, in all future periods of this commonwealth, to cherish the interests of literature and the sciences, and all seminaries of them."

## A ROSE BY ANY OTHER NAME

THE ability to smell has been under investigation in New Haven, and certain revolutionary discoveries in this direction have been released by the Yale University News Bureau. The sensation of smell, apparently, does not come from chemical reactions set up within the olfactory organ by odorous substances that impinge upon it, but results rather from impulses sent out from the organ at extremely high frequencies, as from a radio transmitting station. Smell, because of highly scientific researches made with the common cockroach and the busy bee, has moved into the realm of radiation physics.

The high-frequency impulses emanating from the olfactory end organ, like one way radar waves, fall within a detectable range of 8 to 14 microns. Substances falling outside this range—such, presumably, as carbon monoxide—cannot be smelled by human beings.

The theory of this new concept of smelling is based on the idea that heat moves toward a source of coolness. The olfactory organ is 'hot', the odorous gas is "cool." As the sense organ loses heat the gas gains it, when a balance is reached we become insensitive to the odor. Further work is expected to establish a smell spectrum in which the four thousand to six thousand odors detected by the human nose can be plotted. Thus the guesswork can be removed from smelling.

Smelling distances have apparently not yet been measured, and such naïve predictions as "smelling to high Heaven" will presumably remain in the realm of the unexplored. Nor has the intransitive form of the verb received its full share of scientific recognition. Studies on the ability to smell in this sense remain commercial and seem still to be restricted to those exquisites of radio pronunciation, the foghorn voices that, in a perfectionism of vulgarity, suggest the employment of certain cleansing mediums in the interest of social acceptance.

for the hopeful patients tend to block the exits of the institution. The lives of imbecile children with brains undeveloped or irreparably damaged, whose only hope is death, are prolonged through the conscientious use of prophylactic inoculations against childhood infections. Thanks to the sulfonamides and penicillin, pneumonia is no longer the friend of the aged to the extent that it once was. Tuberculosis, formerly a 10 or 12 per cent contributor to death in institutions, is under control at Monson. A recent survey by means of chest films disclosed less tuberculosis than in the outside population.

However, the decrease in exits because of death has been less in recent decades than the decline in the discharge of living (usually improved) patients. One reason may be the retention of the more able adult patients, which helps to keep down the cost of services. Doubtless a careful survey of patients would disclose a number whose seizures are under control and who might return to the family or the community and make way for patients more urgently in need of hospital care. Such a survey and resulting placements would require the professional help of social workers. At present the hospital staff and the 1400 patients have not a single social worker to help them in their multiplied social problems, although formerly Monson was adequately supplied — a circumstance that may account for the greater rate of discharge at one time. Doubtless each dollar spent in salary and adequate working conditions for competent social workers would save many dollars now lost through a stagnating pool of patients. A "total push" method of medical and social therapy would probably enlarge the outlets of the pool and permit the entrance of actively epileptic adult patients able to do the work of those discharged. During the past year, deaths numbered 54, and discharges 74. The total of 128 is approximately 10 per cent of the patients, which means residence for an average period of ten years, at a total cost per patient of at least \$5000, of which approximately \$250 is paid by the patient or his family.

However, the greatest long-range saving of money and release from the pressure of applicants should come from decreased need for institutionalization. As a money and health saver, prevention far out-

measures treatment, especially in epilepsy, in which a few capsules of medicine a day may mean the difference between social dependence and independence. Early diagnosis and institution of proper medical and social therapy for patients would prevent many a patient from ever entering Monson and becoming a public charge. Massachusetts has led the world in research, in drug therapy and in lay support of epileptic patients. In recognition of this fact, a National Veterans Epilepsy Center has been established at the Cushing Veterans Administration Hospital at Framingham. Contact with this group of patients, whose prognosis regarding both seizures and social usefulness is good, would increase the interest and the spirit of the medical, nursing and social-therapy staffs of Monson.

The second domain of importance for epilepsy and the most fundamental to the proper care of patients is the attitude of the general public. When the public realizes how much can be saved in dollars and in tears through medical research, through early and intelligent treatment of persons subject to seizures and through preventive measures intelligently applied (eugenics, better obstetrics, fewer childhood infections and fewer industrial, automobile and war injuries) enterprises now only dreams will quickly become facts. Experience has shown that public sentiment is changed only when groups of interested persons deadly in earnest get behind a program of enlightenment. This has happened for the epileptic patient in the organization of the American Epilepsy League, with an affiliated New England chapter with headquarters at 50 State Street, Boston. The New England Epilepsy League, which acts as a leaven in the otherwise unresponsive dough of public opinion, inspired the survey of Massachusetts doctors reported in this issue of the *Journal*, as well as a survey of all schools of higher education in the United States reported in the current issue of *Epilepsia*. It seeks to overcome prejudice among educators and employers and to aid phy-

excruciating kind. Yet after long years it is admitted that no real progress has been made. If anything has been proved, it is the utter futility of all this shocking cruelty.

This is the same profound thinker who observed at a State House hearing a year ago

Insulin is a dangerous thing. A man who becomes addicted to it is a slave, more or less to the continuous treatments and all that. Some people assert that it has a very deleterious effect. The statistical tables are contradictory about it.

In the January, 1947, issue of *Living Tissue* appeared an interesting item captioned "The Oxford Case"

A sordid incident which should be "prescribed reading" for those who ignore the evils of vivisection and naively trust the word of those who defend it, is reported from no less a [sic] famous institution of learning and citadel of culture than Oxford University. It seems that Edward George Taody Liddell Professor of Physiology was convicted of cruelty to cats. *His appeal was disallowed* [italics mine]. Excerpts from a commentary on the case which appeared in the November issue of the English publication, *The Cat* follow

The excerpt stated that Professor Liddell was charged and convicted in May of cruelty to some thirty-six cats. The RSPCA was congratulated for prosecuting and winning the case.

A review of four clippings from the London *Times* helps to freshen the air. The last of these, under date of October 11, 1946, is most significant. It states that "none of the allegations at the Oxford City Quarter Sessions was proved against Dr Liddell except that of overcrowding and, therefore, he (The Recorder) would reduce the fine of £25 imposed by the city magistrates to £5." Even this patent sop to the antivivisectionists hardly warrants the language used in *Living Tissue*.

The New England Anti Vivisection Society has a particular fondness for quoting "the late Dr Henry J. Bigelow, Professor of Surgery at Harvard Medical School and long associated with the Massachusetts General Hospital." The "late" Henry Jacob Bigelow (1818-90), speaking of animal experimentation as he observed it at the Veterinary School at Alfort, France, some thirty years before the advent of ether anesthesia, stated before the Massachusetts Medical Society on June 7, 1871, "There will come a time when the world will look back to *modern* [italics mine] vivisection in the name of science as they now do to burning at the stake in the name of religion." The blithe disregard for the dictionary definitions of such terms as "late," "cruelty" and "torture" is rather characteristic of our opponents.

Another look at the record is in order. The "late" Dr. Bigelow wrote a letter to *Our Dumb Animals*, the publication of the M S P C A. This letter stated "The dissection of an animal in a state of insensibility is no more to be criticized than is the abrupt killing of it, to which no one objects. A painless experiment upon an animal is unobjectionable."

His son, William Sturgis Bigelow, wrote in a letter to the Editor of the *Boston Herald* on December 13, 1921

My father was extremely active in securing the physiological laboratory for Harvard University. He did as much as anybody to secure that very laboratory, where then, and now, animal experimentation is carried on when necessary and where results have been obtained which have been of vital benefit to the human race.

The dentist Morton first tested ether on his dog. Walter B. Cannon, pioneer in x-ray examination of the alimentary tract, worked with a bismuth salt on cats. The surgery of Elliott C. Cutler on the valves of the heart and the work of Lennox in epilepsy, of Gross in congenital heart defects and of Harken in wartime wounds of the heart and great vessels would have been impossible without the contributions of animal research in Massachusetts.

Our opponents state that only relatively few physicians have any stake in animal experimentation. This clever "divide and rule" stratagem must be strongly opposed. In our writings the background of animal studies should be stated. Our speakers must stress this vital subject. And above all our patients must be informed. It takes but a moment to tell the animal background of such drugs as digitalis, adrenalin, Dilantin and the rest.

A bill has been filed before the Massachusetts legislature. The Nolen-Miles Pound Law, Senate Bill 264, is pending before the Committee on Legal Affairs. This bill will make unclaimed and unredeemed animals from public pounds available for medical teaching and research. Pets given over to animal pounds for execution are excluded from the provisions of the bill. The six-day period provided by law for the recovery of lost pets is maintained.

Relatively few of the thousands of dogs and cats executed annually in local pounds are required by our medical schools and hospitals. These will be humanely treated. It is their privilege to serve as the K9-corps dogs did in wartime—for the protection of their human masters. Benefits will be obtained that are for the preservation of life and the relief of suffering of both man and animal.

We have repeatedly justified our conduct of the priceless privilege and heritage of animal experimentation. No law has been passed to restrict our humane teaching and research. We can no longer continue our necessary work without extreme difficulty and unwarranted expense. We appear before the legislature with clean hands and unselfish motives.

Our opponents profess to be humanitarians. They would protect and benefit the dog and cat. Our higher humanitarian sentiments must prevail. We protect and benefit the dog, the cat and the human being.

## WHICH TYPE CESAREAN SECTION?\*

ROY J. HEFFERNAN, M.D.,† AND CHARLES LEAVITT SULLIVAN, M.D.‡

BROOKLINE, MASSACHUSETTS

ABDOMINAL delivery may be accomplished in one of three ways by the classic technic, by the low-segment operation or by some form of extra peritoneal cesarean section. It is not possible to compare absolutely the safety of the various procedures because of the variance in skill of individual operators and hospital equipment and also because the results reported by individual operators and clinics are not standardized so far as the condition of the patient at the time a particular technic was chosen for abdominal delivery is concerned.

The classic method results in the highest morbidity and mortality because the uterine incision is the only barrier between the peritoneal cavity and the interior of the uterus, which, as repeated studies have shown, may be invaded by pathogenic bacteria soon after delivery. The classic technic tends to form more adhesions than the other types, and rupture of the uterus occurs more frequently in subsequent pregnancies. The low-cervical operation has a better record. With the development of a bladder flap there is a double barrier to the spread of infected uterine contents. The uterine incision is well covered by peritoneum, adhesions are less likely to form, and the incidence of future rupture is less. We have collected a series of 14,776 low-segment operations reported in the literature in which the mortality was 1.52 per cent, whereas 15,030 patients subjected to classic sections by the same operators and under similar hospital conditions had a mortality of 3.87 per cent (Table 1). It is therefore apparent that, in general, the low-segment operation is over twice as safe as the classic and has fewer subsequent complications. These figures are even more impressive when it is considered that the low-segment operation was frequently selected because the patient was potentially infected. The low-segment or low-cervical cesarean section is usually a safe and satisfactory procedure

when done electively, when patients have been in labor for ten hours or less, with intact membranes, and when there have been no vaginal examinations. Since the incision in the uterus can be thoroughly

in such cases the lower-segment operation does not offer sufficient protection against peritonitis

Seventy-five per cent of deaths from cesarean section occur from infection or hemorrhage, and the remainder from the complications of major surgery or conditions existing prior to the section and possibly aggravated by it. Peritonitis can occur without hemorrhage, which, when present,

always predisposes to infection. The advances of chemotherapy and the development of the antibiotics will control most infections, but mothers still die from peritonitis in spite of adequate treatment by these agents. Many of these patients have been attacked by organisms, such as the anaerobic nonhemolytic streptococcus, that are resistant to these drugs. In a series of 1887 cesarean sections

reported by Irving<sup>25</sup> from the Boston Lying-in Hospital, covering a period of ten years from 1934 to 1943, 42 per cent of the total number of deaths were due to peritonitis.

When actual signs of infection, such as fever, a rapid pulse and a foul amniotic discharge, are present before delivery, any type of transperitoneal section is definitely contraindicated. In 1933 DeLee<sup>40</sup>

wrote "My opinion is firm laparotrachelotomy for all, but in those where infection is suspected, then Latzkos, Porro, or craniotomy."

To consider these procedures in reverse order, craniotomy on the living child is mentioned only to be vehemently condemned. It has no place in modern obstetrics, and the claim that sacrifice of the baby saves the mother is disproved by the experience of Baird,<sup>41</sup> who reports a maternal mortality of 7 per cent in 147 cases of craniotomy. Cesarean hysterectomy for infection adds operative shock and additional blood loss to that of a cesarean section, and if the patient is a young primipara the loss of the uterus may indeed be tragic. We have collected from the literature a series of 119 cesarean hysterectomies done for infection, with a mortality of 14.2 per cent (Table 2). We believe that cesarean

hysterectomy has no place in the treatment of infected patients and should be reserved for parturient patients with fibroids, atonic uteri or other pathologic conditions of the uterus.

Although the morbidity and mortality for abdominal delivery in cases of infection, both potential and actual, have improved since the advent of the antibiotics, chemotherapy and well stocked blood banks, the relative safety of the classic, low-segment and extraperitoneal types of section remains the same. When potential or actual infection exists neither the classic nor the lower-segment operation, even with the antibiotics and chemotherapy, affords the patient the full measure of protection.

The extraperitoneal approach, the principles of which were first expounded over a hundred years ago, is the safest method of abdominal delivery. In 1821 Ritgen<sup>51</sup> first tried to approach the lower anterior extraperitoneal surface of the uterus from the lateral aspect of the bladder through the paravesical space. Fundamentally the operations of Baudeloque,<sup>52</sup> Thomas<sup>53</sup> and Latzko<sup>54, 55</sup> fall into the same group. The commonly accepted technic, until the presentation of Waters<sup>56</sup> and Ricci,<sup>57</sup> was

that described by Latzko. We have collected from the literature a series of 1145 cases in which Latzko sections were performed, with a mortality of 3.4 per cent (Table 3). Although, as noted by the authors, the collections of classic and low-segment operations contained an admixture of clean, potentially infected and infected cases it is probable that this series consisted entirely of potentially in-

The modern concept of the extraperitoneal approach lies in the principle first expounded by Physick of Philadelphia to DeWees<sup>66</sup> in Horner's letter in 1824. This suprapubic approach was not attempted until Frank<sup>66</sup> and later Sellheim<sup>70</sup> unsuccessfully tried it. The same approach is the basis for a series of operations presented by Waters<sup>68</sup> in January, 1939, with one radical difference: the

FIGURE 1

*The upper left illustration demonstrates a low suprapubic incision (extending from 5 cm. below the umbilicus to the pubis)*

*The lower left illustration shows a sagittal view (the double lines indicate peritoneal reflections)*

*The right illustration demonstrates an incision to the transversalis fascia showing separated recti and a distended bladder*

fectured cases. Nevertheless, the mortality was less than that in cases in which the classic technic was used. However, the Latzko operation was always difficult and rarely presented an adequate space through which the baby could be delivered, and tears of the peritoneum and injuries to the ureters, bladder and uterine vessels frequently occurred.

plane of dissection. Previous operators had attempted to peel the peritoneum from the bladder and pelvic fascia, and Waters showed that the proper technic was to lift the peritoneofascial flap as a unit. Ricci and Marr,<sup>71</sup> in an excellent monograph, present a clear description of the anatomy of the area, as well as a detailed discussion of their

method Norton<sup>72</sup> describes a procedure that lies between the old Latzko operation and the methods of Ricci and Marr and Waters, in that the bladder is not completely separated from the peritoneal fold, the approach being paravesical and the dis-

effect by keeping it localized to the uterus. Naturally, the antibiotics and chemotherapy are employed when indicated.

In 1942 we began to use this operation in actually or potentially infected patients, and we have been so impressed with its value that we frequently employ it now in clean, elective cases. Figures 1 to 8 outline the salient features of the technic.

Although any anesthetic may be used, we have preferred small doses of spinal anesthesia—the

FIGURE 2 Right Rectus Muscle Retracted Laterally, Exposing the Paravesical, Yellow, Chicken Fat Pad, Lateral to the Base of the Bladder

placement medial. The approach today involves either the complete or incomplete dislocation of the bladder from its lower-segment bed, its displacement downward or medially after complete or incomplete separation from the peritoneal fold, resulting in an adequate extraperitoneal approach to the lower uterine segment. Since the first presentation of this modern method we have been able to collect from the literature a series of 1089 cases of extraperitoneal cesarean section with a mortality of 0.8 per cent (Table 4). It is important to note that there were deaths from sepsis. It is clear, then, that this operation is not offered as a cure for infection, but rather to prevent the spread of actual or potential infection and to minimize its

FIGURE 3 Paravesical Fascia and Fat Pad Separated and Finger Inserted between the Posterior Surface of the Bladder and the Lower Uterine Segment (the Procedure is Repeated on the Other Side)

danger of doses of average size in obstetrics is too little realized, and we urge the selection not only of a competent anesthetist but also of a minimal dose of the drugs employed. We use 50 mg of novocain crystals and 5 mg of pontocaine in 2 cc of spinal fluid. Injection is made in the fourth interspace without barbiturates, unless the operation is prolonged for any reason, when a small amount of

intravenous barbiturate or inhalation anesthesia may be used as a supplement.

We have made use of this operation in 72 cases to date, and in our experience there has been no fetal or maternal mortality. The most impressive feature, however, has been the complete absence of postoperative morbidity. Such patients may eat within six hours of operation and have no nausea, no vomiting or "gas pains" and no more distention than occurs after a normal delivery from below. When indicated ambulation may be permitted as soon as the effect of the anesthesia has subsided.

As we grew familiar with this technic and realized through experience that the operation itself presented no hazard to the mother we gradually

*Ruptured membranes.* The procedure is indicated in any case in which the membranes have been ruptured for a period of eight hours. Although this duration is arbitrary, amniotic infec-

FIGURE 4. Incision Started through the Transversalis Fascia below the Peritoneal Reflection

widened our scope of indications, and at the present time we use it for the following conditions:

*Infection.* We consider the operation indicated in any patient in whom there is the slightest suspicion of infection, either genital or extra-genital. Dehydration fever can easily be diagnosed and eliminated by proper treatment.

FIGURE 5. Lower Uterine Segment Exposed—Peritoneofascial Fold Retracted Upward, Bladder Mobilized and Drawn Downward

The sagittal view shows the lower uterine segment exposed extraperitoneally. The double line indicates the peritoneal fold now completely separated from the bladder.

tion may be present in an early stage without systemic reaction.

*Labor.* Actual infection of the uterine cavity potentially starts with the onset of labor, and there is no method of absolutely eliminating cases that are free of infection. Any patient in labor for six hours or longer should have the added insurance of this procedure. Harris and Brown<sup>22</sup> found no sterile cultures of the lower uterine segment at operation when labor had lasted six hours or more.

*Vaginal examination.* The operation is performed in patients who have had vaginal examinations or repeated rectal examinations.

*Unsuccessful trial at pelvic delivery* When it is found that an attempted forceps operation can be concluded only with serious damage to the mother or the baby, or both, the forceps should be removed, and an extraperitoneal cesarean section performed. Irving<sup>25</sup> has shown that

qualities, such as those suffering from malnutrition or avitaminosis, are best protected by the extraperitoneal approach to prevent wound dehiscence and evisceration with its attendant high mortality—an event occurring in about 1 in 600 cases.<sup>25</sup>

Patients at or near term, when the lower uterine segment is well developed, are the best subjects for this operation. We have done the operation as early as thirty-one weeks. It can be performed with ease on patients not in labor. Drainage is performed only in patients believed to be actually

FIGURE 6

*Transverse incision in the thin layer of the anterior uterine fascia permits the peritoneofascial fold to be displaced cephalad. This allows adequate exposure to the lower uterine segment, even though the patient has not been in labor. The bladder has dropped beneath the symphysis-Doyen retractor shown in position.*

at the Boston Lying-in Hospital a difficult mid-forceps operation can be almost as dangerous to the mother as an intraperitoneal cesarean section—and about eight times more dangerous to the baby.

*Previous phlebitis or extensive varicosities* Earlier ambulation after the extraperitoneal operation is a definite advantage in the patient with a history of previous phlebitis and extensive varicosities.

*Poor surgical risks* This category includes all patients generally regarded as poor surgical risks—that is, those with chronic respiratory infection or severe pre-eclampsia. The correlation between blood loss and sepsis is well known, and we have done this operation in placenta previa and separated placenta with this thought in mind. Patients suspected of poor healing

FIGURE 7 *Curved Incision of Lower Uterine Segment Started, Exposing Amniotic Sac. Note the pronounced convexity.*

infected, a “fish-tail” drain being applied to the uterine incision, this is withdrawn on the fifth day. The bladder is placed on constant drainage for a period of twenty-four hours, after which all patients have been able to void spontaneously without retention.

#### SUMMARY

Although better obstetric management, improved operative technic, replacement of blood loss and the

advent of chemotherapy and the antibiotics have considerably lowered the incidence of peritonitis after cesarean section, the complication still occurs, especially after the classic procedure. This type of abdominal delivery has so many disadvantages that

classic, it is not without danger in the potentially infected case, since it does not ensure protection against peritonitis from the spill or seepage of infected uterine contents.

Craniotomy on the living child is never justifiable

FIGURE 8. *Sagittal view Demonstrating Extraperitoneal Extraction Effected by the Use of the Fingers as a Tactus Assisted by Suprafundic Pressure*

A shows a similar anterior view

B shows the uterine incision closed and the bladder re-filled to check integrity

it should be used only when better methods are not applicable or when the uterus is to be removed.

The lower-segment operation is a very satisfactory type of abdominal delivery in uncomplicated, clean cases, and although over two times safer than the

Cesarean hysterectomy should be used only when some pathologic condition necessitates the removal of the uterus.

The modern extraperitoneal operation not only is the safest technic for the infected or potentially

infected parturient patient but also may be used to advantage for less imperative indications

## THE WORK OF A PHYSICAL-FITNESS CLINIC

WILLIAM R P EMERSON, M D \*

BOSTON

THIS is a report of a physical-fitness clinic conducted at the Massachusetts headquarters of the Blue Cross among approximately 900 executives and employees

The personnel conducting the clinic consisted of one experienced physical-fitness worker, three physicians, part time, especially trained to make physical examinations to detect not only disease but also any physical defects that might cause impaired health, and a secretary trained in statistics, to tabulate results and to act as receptionist and make appointments. I supervised the work and saw problem cases one morning each week.

The physical-fitness worker and the secretary were on full time. One of the three part-time physician worked six hours a day for one day and three hours a day for four days each week.

## PROCEDURE

Every applicant to the clinic was given a health examination, with the object of identifying the causes of impaired health. This examination was uniform, over a hundred factors relating to the causes of health impairment being checked.

The examination consisted of a health history of the applicant, a check-up of twenty of the most common faulty health habits, a check-up of the daily program for twenty-four hours in a typical day, a check-up of all food taken in a twenty-four-hour period and a physical examination to detect not only actual disease but also any physical defects that might impair health.

The time given to each health examination and directions for the correction of both physical defects and faulty health habits was exactly sixty-five minutes. Two applicants were examined each hour, or 36 a week. The remaining time of the physical fitness worker was devoted to return visits, especially to those who were in the danger zones of overweight and underweight. Because of the relation of weight to mortality, recognized in insurance work by rejection or substandard ratings on this factor alone, the group was separated into three divisions: overweight, optimum weight and underweight.

The optimum weight zone was determined by the range of lowest mortality found in the *Medico-Actuarial Table* of 1912 (Fig 1). This zone extends approximately from 5 to 15 per cent above average weight and closely corresponds with that determined by clinical standards and individual health experience. Overweight includes those above optimum

weight, and underweight those below optimum weight.

## WEIGHT STATUS

In a period of approximately six months, 735 executives and employees, seventeen to sixty-three years of age, received this health service. The findings are presented in Table 1.

## FAULTY HEALTH HABITS

Health habits that deprived the subject of one or more of the essentials of health — namely, fresh air and sunlight, proper food and food habits, regular exercise and proper rest — were considered faulty. To these must be added regularity of living habits, which is a fundamental factor in acquiring physical fitness.

The faulty health habits found by a check-up on each applicant are presented in Table 2.

The faulty health habits found in each weight zone are presented in Table 3, which demonstrates that applicants of normal weight had fewer faulty health habits than either the overweight or the underweight subjects. The most frequent faulty habits of the overweight applicants were no regular rest periods, insufficient exercise and outdoor sunlight, fast eating, habitual overeating and candy between meals. Those of the underweight group were no regular rest periods, insufficient exercise and outdoor sunlight, fast eating, candy between meals and irregular bedtime.

## PHYSICAL DEFECTS

The physical defects found are presented in Table 4. Each employee was referred to his own physician or dentist for defects needing correction. Thus, 197 (27 per cent) applicants were referred to family physicians, and 124 (17 per cent) to family dentists.

When his faulty health habits had been checked and the physical examination completed, the applicant was told what health habits and what physical defects were found, and their effect in impairing his health was explained. He was also told that both overweight and underweight were unnecessary and that by correcting his habits that were essentially faulty he could improve his health and thus add years to his period of active work and efficiency.

He was then asked this question: "Are you interested in planning your day's activities to correct these defects and to work for better health?" If he said he was interested, it was suggested that he weigh in each week, and he was told that he would be helped to plan his daily program to attain better health.

\*Director, Physical Fitness Clinic, Blue Cross, formerly director, Physical Fitness Clinic, The Life Insurance Company and Dartmouth College.

## RETURN VISITS

After the examination had been completed, the applicant was offered an opportunity to return each

735 applicants taking the service answered "No" Yet, when their daily programs were checked up, a total of 2294 faulty health habits were found — an average of 3 1 habits that needed to be corrected

The response to the offer of an opportunity for return visits was so great that soon it became necessary to reduce the number of initial examinations to take care of the return visits In the limited time of the demonstration, the number of return visits

TABLE 2 Faulty Health Habits (All Applicants)

FAULTY HEALTH HABITS	NO OF CASES	PER CENTAGE
No regular rest periods	717	98
Insufficient exercise or outdoor sunlight	273	37

faulty health habits and secure the essentials of health

In answer to the question, "Have you any health habits that are injurious to your health," 730 of the

made by those interested in working for a higher standard of health was 2822

At each return visit, the applicant was weighed and his diet list checked, and suggestions were made

TABLE 3 Faulty Health Habits According to Weight of Applicant

STATUS OF APPLICANTS	NO OF CASES	FAULTY HEALTH HABITS	
		NO OF CASES	AVERAGE
Overweight	164	559	3 40
Normal weight	239	687	2 87
Underweight	332	1048	3 15
Totals	735	2294	
Average			3 10

for rearranging his daily program to ensure him essentials of health

The time given for each return visit from the time of entering the clinic to the time of leaving was an average of eight minutes

In this demonstration, as elsewhere, the return visits were found to be of great importance, because habits of daily living are determined not by the requirements of healthful living but by individual family life, working conditions, social life and diver-

sions that, from the standpoint of health, may be dissipations

Directions for improving health were given by the physician and physical-fitness worker together, on the basis of the findings recorded on the examination form. Directions were given as definitely as those given by the physician after he makes a diagnosis of disease.

The success of the applicant in gaining or losing weight, in reducing his blood pressure and in increased efficiency and improvement in general well being kept him returning to the clinic until his objective had been attained. He was made to understand that the job was his, and that better health could be won only by his own efforts.

## RESULTS

### Overweight Applicants

It was suggested to the overweight applicants that they reduce their weight slowly, the reduction not to exceed an average of 1 or 2 pounds a week until they got out of the danger zone of overweight indicated in Figure 1 — the men, until the abdomen ceased to be prominent and the women, until the folds of fat disappeared from about the waist and hips.

The weight reduction accomplished in the limited time of the demonstration varied from 2 to 27 pounds, a total of 574 pounds.

The following case provides an example.

J. M., a 19-year-old girl had always been overweight and retained being called fat. She had tried various methods of reducing her weight without success. By reducing her diet (calories) to a point where she lost about 15 pounds a week she reduced her weight 27.5 pounds. During that time, she did not suffer from hunger after the 1st week and considered the diet that met her needs no special hardship.

### Underweight Applicants

The underweight applicants were found to have more faulty health habits than either of the other groups. Their daily programs showed almost continuous nervous tension, caused not so much by the pressure of work as by continuous activities outside working hours and on Saturdays and Sundays.

Their gain in weight during the time of the demonstration ranged from 2 to 14 pounds, a total of 246 pounds.

An example is afforded by the following case.

E. C., a 19-year-old girl was attractive and ambitious. She was working overtime 1 or 2 nights a week and studying designing 2 nights a week. She had no physical defects. Her faulty health habits were those of taking no rest periods during the long day and taking a light breakfast and a light lunch, and eating a hearty dinner at night when overtired. She was advised to take a complete rest lying down for 20 minutes before her evening meal and on Saturdays and Sundays to have her breakfast at the regular time, resting in bed until noon and utilizing the afternoon for outdoor exercise and sunlight. She was able to continue night and overtime work and gained 14 pounds — attaining normal weight for her height.

### Hypertensive Applicants

There were 12 cases of hypertension, the blood pressure ranging from 150 to 210 systolic and from 90 to 110 diastolic.

By loss of excessive weight and relief of high-pressure living by twenty-minute periods of complete rest before the evening meal, and by correction

of faulty health habits, the reduction in systolic blood pressure averaged 20.

The faulty health habits in these cases were those of habitual nervous tension, insufficient exercise and outdoor sunlight and fast eating.

The following cases are illustrative.

H. M., a 56-year-old man weighed 191 pounds. He had recovered from a heart attack but was short of breath on slight exertion. His heart area was enlarged and a systolic heart murmur was heard over the entire pericardium. His faulty health habits were habitual overeating, worry, no rest periods and the candy habit.

He reduced his weight 13 pounds and his systolic blood pressure from 210 to 146. He was able to continue his regular work without untoward symptoms. In the meantime he was referred to his own physician for a more careful supervision of his heart condition.

D. R., a 50-year-old woman weighed 159 pounds. Her blood pressure was 150/50. She reduced her weight 25 pounds and her blood pressure returned to the normal of 116/82.

These findings and results closely parallel those observed in a group of 100 consecutive cases of hypertension reported in September, 1938.

### *Absenteeism*

All executives and employees were circularized before the work began. Therefore, an adequate control group was not available to compare days off from sickness.

However, a study of 100 employees taking the service and of 100 before taking the service (matched by five-year age ranges, by sex — 26 women and 24 men — and to some extent by employment status) showed a reduction of 26 per cent in days off from sickness for those taking the service,<sup>3</sup> as compared with 46 per cent in a large group elsewhere<sup>4</sup> when controls were complete.

### DISCUSSION

Because of the loss to industry caused by absenteeism, and because of the greater loss in lessened efficiency of the workers when on duty, it is only logical that definite steps should be taken to prevent sickness. The success of the physical-fitness service in accomplishing this purpose, wherever tried, has demonstrated its value.

The cost of the service is relatively small because the bulk of the work is done by a lay person, the trained physical-fitness worker. One such person, with the part-time aid of a physician and a secretary, is able to conduct the service for a group of from 1800 to 2000 persons and handle from 4000 to 5000 return visits a year.

Patients are willing to pay for medical service when they are sick but not for health service when they think they are well. Therefore, the expense must be borne by the employer. The employer is justified in assuming this expense because of resulting reduction in absenteeism, increased efficiency and improvement in morale.

To the cost of days off for sickness must be added the loss from lessened efficiency, for when health is impaired the higher powers are first affected — judgment, initiative, endurance and personality. This loss is most evident among the higher paid executives, on whose efficiency the success of the industry rests.

True health examinations, which are necessary for successful health work, are not now available because the usual so-called "health examination" is an examination for disease. Thus, to obtain its benefits, the subject must be sick before he can be well.

The physical-fitness clinic functions as a screening clinic not only to determine the causes of impaired health but also to identify disease and send such patients to their own physicians and dentists.

The number of physical defects and faulty health habits and the number of return visits of the female employees were in like proportion to those of the males.

The twenty-four-hour list of activities demonstrates the helplessness of the average person in planning his day to conform with the essentials of health. The fault lies not so much in working con-

ditions, in the improvement of which industry has made epochal advances, but chiefly in the time off from work — especially Saturdays and Sundays, which are usually periods of irregularity and of activities that make for dissipation of health reserves, rather than of recuperation. Hence, "Black Monday" is proverbial in industry.

By his return visits to the clinic, the applicant is encouraged and receives the fundamental health instruction necessary for him to obtain optimum results. During the period when he is working for better health by correcting his faulty health habits, he forms good health habits that continue throughout his working life, for good habits are as persistent as faulty ones.

The physical-fitness clinic, properly conducted, brings to the patient not only the resources of present-day medical knowledge but also the newer knowledge of factors contributed by allied science — especially those relating to the functions of the body as affected by irregularity, overfatigue, lack of sunlight and disturbed physiologic processes.

The diagnosis of health is a challenge to the best skill of the physician — as stated by Theobald Smith, "The diagnosis of health is more difficult than the diagnosis of any disease."

The desire for better health is universal, and the patient needs only to be convinced that habits are really faulty, and to receive definite directions for correcting them, to co-operate willingly. His success makes the atmosphere of the clinic a happy one both for himself and for the clinic workers — all striving for a common purpose.

### SUMMARY AND CONCLUSIONS

A physical-fitness service offered to approximately 900 executives and employees of the Blue Cross at their Boston home office is described.

The results obtained answered wholly or in part the following questions:

To what extent were they interested in working to improve their health?

Attendance at the clinic was voluntary except for 313 new employees who entered the organization with the understanding that they would be required to have the health examination and return once a year for a check-up, 422 of the remaining old employees applied for the examination — a total of 735.

Did they know they had health habits essentially faulty?

Only 5 applicants answered in the affirmative when asked, "Have you any health habits injurious to your health?" Thus 730 were unaware that they had such faulty health habits, although when checked 2294 were found.

When faulty health habits are identified, will they correct them?

In the six-month period, 2822 return visits were made by those working to correct them.

If they work to correct these habits, what results can they obtain?

Their improved health was the cause of the continued visits. A partially controlled group of 100 applicants showed a reduction of days off from sickness of 26 per cent, as compared to a reduction of 46 per cent in a similar group in which controls were complete.

Eighty-eight cases in the danger zone of overweight lost from 1 to 28 pounds, a total of 574 pounds. Eighty-eight cases in the danger zone of underweight gained from 1 to 15 pounds, a total of 247 pounds, and 14 patients with systolic pressures ranging from 150 to 210, were found, at the end of the period of return visits, to have reduced the systolic pressure an average of 20.

Of the 735 applicants examined, 110 had no physical defects aside from overweight and underweight. None were entirely free from faulty health habits.

Twenty-seven per cent were referred to their family physicians, and 17 per cent to their family dentists.

A check-up of their twenty-four-hour periods of activity showed that faulty health habits were oc-

casioned chiefly by conditions outside rather than during working hours.

The clinic demonstrated that both executives and employees need only to have their faulty habits identified and definite directions given for their correction to obtain efficient co-operation in working for better health.

I am indebted to Mr. R. F. Cahalane, executive director of the Blue Cross, for the invitation to conduct this clinic and to Mr. H. Proctor Redd, director of public relations, Mr. Harry Healy, director of personnel, and Dr. Charles G. Hayden, medical director, Blue Cross, for their cordial cooperation.

Personnel of the clinic included Albert C. England, M.D., examining physician; George M. Olive, Jr., M.D., and L. Murray Shipp, M.D., examining physicians; Helen M. Sanderson, physical fitness worker; and Martha Freedman, secretary and statistician.

## MEDIAL PTOSIS OF THE KIDNEY\*

### A New Renal Syndrome

GEORGE C. PRATHER, M.D.†

BOSTON

**P**ROBABLY on more than one occasion urologists have examined patients for pain or discomfort that, because of its character and location, was thought to be of renal origin, only to find the pyelographic studies normal. In at least a few of these cases the symptoms may be due to medial ptosis of the kidney.

Caudal mobility of the kidney with the body in the vertical or upright position (ptosis of the kidney) has been known for many years as a clinical entity, with alternate periods of popularity and disrepute. This paper is not directly concerned with that subject.

Little or no attention has been given to medial or lateral mobility of the kidney, and the pyelographic demonstration of an abnormal degree of medial mobility has not, to my knowledge, been previously described. "Medial ptosis of the kidney" has been chosen as a term to describe abnormal medial mobility of that organ. With a patient lying on the left side the condition of medial ptosis of the right kidney would be shown by abnormal change of the position of the right kidney toward or beyond the vertebral column. Similarly, medial ptosis of the left kidney might be demonstrated with a patient lying on the right side.

This condition, which may be the cause of symptoms, cannot be demonstrated by the usual pyelographic technique. The diagnosis can be made, however, by means of x-ray films using anteroposterior projection with the patient in the lateral position (Fig. 1). After cystoscopy and ureteral catheterization or during intravenous pyelography the patient is placed on a litter lying on his side, with the painful side up. The patient's back is placed firmly against an upright x-ray table used for gastrointestinal or chest x-ray examination, or against a cassette, 35 by 65 cm., in front of which has been placed a portable Sieman's microgrid. The x-ray tube is then focused for an anteroposterior view of the kidney region. A retrograde pyelogram is then made, with the ureteral catheter pulled down into the lower ureter before the x-ray film is taken. A routine film taken in this position during intravenous pyelography may be used instead.

To determine the normal extent of medial mobility of the right kidney with the patient lying on the left side, films were taken in the position shown in Figure 1 after pyelographic studies had been completed in a number of patients. As illustrated in Figures 2 and 3, these studies showed no medial descent of the kidney in the normal person.

\*Presented at a meeting of the American Association of Genito-Urinary Surgeons, June 5, 1947, Atlantic City, New Jersey.  
†Resident-in-charge for urology, Boston City Hospital.

‡Manufactured by the Libel Fl. & Co. Company, Cincinnati, Ohio.

The condition of medial ptosis has recently been demonstrated and corrected in 2 patients. Both

were slender women who had moderate pain and distress in the right upper quadrant of the abdomen

FIGURE 1 *Position of Patient for Pyelogram to Demonstrate Abnormal Medial Mobility of the Right Kidney*

*X-ray film taken as an anteroposterior projection, with the patient in the lateral position and with the painful kidney up*

A

B

FIGURE 2 *A Shows a Normal Pyelogram in the Supine Position, and B a Pyelogram of the Same Patient in the Position Shown in Figure 1 (The Right Kidney Remains in Normal Position)*

and the right flank. At times the symptoms were noticed or were aggravated when the patient was lying or sleeping on the left side. Physical activity also frequently produced discomfort. Mild gastrointestinal symptoms appeared to be associated with the pain. There were no urinary symptoms. Both patients had obtained relief by resting in a supine

position. Physical examination in each case was negative, except that a suspicion of an abnormally movable kidney was created by palpation of the upper portion of the abdomen with the patient lying on the left side, and in 1 case the kidney could be felt in the epigastrium while the patient was in a similar position. X-ray studies of the gall bladder,

FIGURE 3 A Shows a Normal Pyelogram in the Supine Position and B a Pyelogram of the Patient in the Position Shown in Figure 1 (The Right Kidney Remains in Normal Position. Note Fluid Level in Kidney)

FIGURE 4 A Shows a Pyelogram of Patient A in the Supine Position and B a Pyelogram of Patient B in the Supine Position

stomach and intestines were reported as negative. Intravenous urograms were likewise normal. The

the extent of caudal mobility with the patients in an upright position — patient "A" shows some,

FIGURE 5 A Shows a Pyelogram of Patient "A" in the Upright Position, and B a Pyelogram of Patient "B" in the Upright Position

question of medial ptosis arose, and special studies of the right kidney established the diagnosis

but not significant, vertical ptosis, whereas patient "B" shows none. From these films it certainly

FIGURE 6 A Shows a Pyelogram of Patient "A" in the Position Shown in Figure 1 — There Is Abnormal Medial Mobility of the Kidney in This Position, B Demonstrates a Pyelogram of Patient "B" in the Position Shown in Figure 1 — There Is Abnormal Medial Mobility of the Kidney, Which Has Dropped Beyond the Midline and Carried the Ureter with It

Figure 4 shows the retrograde pyelograms in the supine position in each patient. Figure 5 reveals

would not be possible to state that the right kidney was the cause of symptoms in either case.

However, by means of films taken in the position described above (Fig 6) a significant degree of medial ptosis had been corrected in each case

FIGURE 7 A Shows a Postoperative Pyelogram of Patient L in the New Position (Kidney Is Now in Normal Position) B Demonstrates by Postoperative Pyelogram of Patient L in the New Position with the Kidney in Normal Position (The Fluid Level in the Kidney and the Fetal Spine Can Be Seen)

medial ptosis of the right kidney could be demonstrated in both patients, patient "B" appeared to have a considerable degree of medial mobility.

Nephropexy was performed on both patients with complete relief of symptoms and postoperative

It is my belief that this syndrome may explain some of the hitherto undiagnosed symptoms referable to the kidney regions and the upper abdominal quadrants. Nephropexy is a simple method of correcting the condition.

## A DEVICE FOR CONTROLLED NEGATIVE PRESSURE

JOHN BRADFORD MILLET, M D \*

BOSTON

**T**HIS article presents a simple compact device for the safe administration of controlled negative pressure to the gastrointestinal tract of patients in institutions having built-in negative-pressure systems

Some of the difficulties and inconveniences previously encountered in the use of suction apparatus

inflow and outflow tubes attached — an arrangement that allows the tops to be easily removed for emptying the bottles and to be easily replaced and made airtight. The bottles fit in a stainless-steel rack, which hangs from the frame of the hospital bed (Fig 1). Thus, the rubber tubing is kept at a minimum, and the device is off the floor and out of the way when the bed is being made or moved.

The overflow bottle (Fig 2) rarely needs opening except when the drainage bottle has been allowed

FIGURE 1 Photograph of the Device in Its Stainless-Steel Rack. This rack was designed and constructed by Mr. Edward Hallinan.

prompted the development of this device. Any apparatus, when on the floor, is likely to be tipped over or broken and makes cleaning of the room difficult. Bulky glass apparatus, if strapped on the bed frame, is likewise often broken. Many rubber tubes leading to and from the apparatus are often draped over the bed and the patient. Glass connectors in rubber-stoppered bottles are easily shattered, and may injure the hands of the attendants.

This device consists of two 2-liter "Atlas" preserve jars, one for drainage and the other for overflow. The bottles are fitted with cast-brass duplicates of the original snap-on glass tops, with brass

\*Assistant resident in surgery, Massachusetts General Hospital

FIGURE 2 Photograph of the Top of the Overflow Bottle, with Its Attachments.

A shows flow-control unit in outflow tube, B leather-covered manometer opening, C adjustment bolt for negative-pressure release valve, D lock nut, and E inflow tube.

to overflow into it. Should the overflow bottle become full, the downward extension of the outflow tube will not permit the fluid level to reach any vulnerable part. The overflow bottle has three special features. The first, a flow-control unit attached to the outflow tube, is a bolt that has been drilled with a small-caliber drill. The resulting small orifice per-

mits the wall valve to be fully opened, since it automatically allows only a small volume of air to flow through the device per unit of time. Careful flow adjustments at the wall valve are therefore unnecessary. The second feature is a mercury manometer incorporated in the device, which accurately shows the observer at a glance the degree of negative pressure in the system. The ends of this manometer are leather covered. One end opens inside, and the other outside the bottle. This arrangement permits no mercury to escape and yet allows sufficient air flow for the manometer to function. The manometer tube is made of "Tenite II," an Eastman Corporation clear thermoplastic that is difficult to break. The connectors must be made of a metal such as aluminum or stainless steel that will not amalgamate with the mercury. The third feature, a negative-pressure release valve, is also incorporated in the device, with a range of adjustment from 0 to 6 inches of mercury — 3 inches of mercury is roughly equivalent to 40 inches of water, which is the usual working range for gastrointestinal suction. The negative pressure release valve is a ball valve with adjustable spring tension. A metal ball sits on top of a spring in the hollow valve housing, and the valve seat is at the base of the hollow adjustment bolt, to which a lock nut is attached. The air intake is beneath the head of the adjustment bolt so that it cannot be inadvertently occluded.

By means of the features mentioned above a system is set up that causes a constant stream of air to flow through the overflow bottle, entering via the air intake and leaving by way of the small orifice in the flow-control unit. The negative pressure in the overflow bottle is variable, being changed by increasing or decreasing the spring tension, which forces the metal ball against the valve seat (Fig. 3). The negative pressure is registered on the manometer and transferred through the drainage bottle to the patient. Variations in the negative pressure in the main hospital system do not affect the negative pressure in this device, provided the negative pres-

sure in the hospital system does not fall below that in the device.

#### SUMMARY

A device for safely administering controlled negative pressure to the gastrointestinal tract of pa-

FIGURE 3 Diagram of the Negative Pressure Release Valve. A demonstrates air intake beneath the head of the adjustment bolt. B lock nut with attached handle for tightening and releasing. C hollow valve housing. D metal ball and E, spring forcing metal ball against the valve seat.

ients is presented. The apparatus is simple in design, and the parts are inexpensive. Its breakable parts are its cheapest and are readily obtainable. It has proved simple to operate for members of the nursing staff who have used it.

## MEDICAL PROGRESS

### THE "NEPHROTIC SYNDROME" (Concluded)\*

STANLEY E. BRADLEY, M.D.,† AND CORNELIUS J. TYSON, M.D.‡

NEW YORK CITY

#### HYPOPROTEINEMIA

The return of the plasma protein concentration toward normal as the urinary protein loss decreases indicates clearly that proteinuria is most important in the pathogenesis of hypoproteinemia. However, there is reason to believe that other factors are concerned in this phenomenon. On occasion the daily protein loss may exceed 30 gm, but usually it lies between 5 and 10 gm.<sup>74, 75</sup> This appears to be relatively small in terms of protein replacement capacity. Co Tu<sup>76</sup> estimates, on the basis of changes observed in animals after plasmapheresis and in human blood donors after repeated blood letting, that normal man should be capable of manufacturing approximately 55 gm of protein per day, provided an adequate diet is given. Some patients with the nephrotic syndrome can maintain a constant (though low) plasma protein concentration by manufacturing at least 20 gm of protein per day to replace that lost in the urine. But others fail to replace even this much, and it may be posited that there is a fundamental impairment of protein synthesis in the nephrotic syndrome that varies quantitatively from case to case.

The evidence regarding this point is confusing, fragmentary and often contradictory. Very few patients can be or have been subjected to the necessary expensive and protracted balance studies. It is very difficult to be sure that the data of different studies are comparable. But it now seems certain that increasing the dietary protein intake does not usually result in augmented plasma protein synthesis. Berglund, Scriver and Medes<sup>77</sup> and others<sup>78</sup> have found that the plasma proteins increase slightly in response to high-protein feeding and that proteinuria may be remarkably exaggerated. Farr<sup>79, 80</sup> and others,<sup>81</sup> on the other hand, failed to find any change.

Similarly, disagreement is evident regarding basic nitrogen needs. In children it appears to be very difficult to maintain a positive nitrogen balance.<sup>79, 80</sup> The optimal intake is not much in excess of the needs of a child of the same age and ideal weight, and only slightly greater protein intake may have a toxic effect by reducing protein assimilation.<sup>82</sup> Ad-

ministration of amino acids, by mouth or, better still, by vein, seems to counteract this effect to some extent.<sup>83</sup> In most adults nitrogen equilibrium is more easily achieved, although utilization of protein is determined by the caloric intake and by the character of the protein and amino acid mixture ingested. The divergencies between nitrogen needs for children and adults may be in part attributable to the factor of growth and, when this is of no importance, to differences in the extent of protein depletion.

The plasma proteins are believed by many workers to be in equilibrium with an extensive "protein pool" the bulk of which is extravascular.<sup>84</sup> Reduction of the plasma protein accordingly denotes reduction of the total labile body protein, and repair of a plasma protein deficit entails replacement throughout the pool as a whole. Very little is known of the measures employed by the body to protect the composition and size of the pool, though it appears that a fall in plasma protein stimulates manufacture and possibly reduces catabolism. Moreover, catabolism is lowered during starvation to a minimum commensurate with intracellular activity and caloric needs.<sup>85</sup> When an adequate caloric intake is assured and only nitrogen withheld, a still greater reduction occurs, though it appears that some 20 gm of protein is destroyed even then each day. It is not known how protein degradation and nitrogen excretion are reduced in starvation, but the same processes are probably operative in the nephrotic patient, since, almost without exception, such patients lose tissue protein and present striking emaciation after removal of edema fluid therapeutically or by spontaneous remission. In experimental animals plasmapheresis has also been found to draw upon proteins essential in hemoglobin production.<sup>86</sup> Perhaps this explains the anemia seen in some cases of nephrosis. Hence, it seems reasonable to regard the nephrotic syndrome as a state of quasistarvation in which nitrogen requirement is reduced to a minimum. Nonetheless, the nephrotic patient has a nitrogen requirement considerably in excess of the sum of the theoretical minimum and the amount of nitrogen lost in the urine, possibly to meet the need of replenishing a depleted protein pool or to replace tissue protein.

It is not quite clear why the protein pool should be depleted. Certainly, many patients continue to have excellent appetites and to consume consider-

able amounts of protein food throughout the course of their illness. It must be assumed that very large quantities of protein are lost in the urine when the plasma protein level is still normal, before symptomatology demands the attention of the physician. Patients may be expected to differ markedly in the extent to which this process has been carried. Thus, in Berglund's<sup>17</sup> series a lag period of several days following the administration of a high-protein diet intervened before increased plasma protein synthesis became evident in a slight increase in plasma protein concentration and proteinuria. This period may represent the time required for the restocking of the extravascular component of the protein pool. In contrast, in only 1 patient studied by Keutman and Bassett<sup>11</sup> did the plasma protein level rise and then only because proteinuria slacked off. Hence depletion may have been more marked in their patients. It is possible, of course, that these observations indicate the inadequacy of the protein pool concept in this connection, since nitrogen may be required for the building of stable proteins as well as labile components of the pool.

Theoretically, the ideal replacement material should be concentrated purified fractions of the human plasma proteins, but unfortunately these substances have often failed to increase protein concentration satisfactorily.<sup>17-19</sup> Nor is there any evidence that protein synthesis is stimulated by the additional protein intake. One difficulty arises from the fact that the injected protein is immediately distributed throughout the protein pool. Luetscher<sup>27</sup> has found that a small percentage of injected albumin appears in the urine, that most of the remainder disappears from the blood within forty hours and that only a small fraction remains in the circulation. When one considers the probable size of the protein pool this behavior is not unexpected. In the starved dog the ratio between extravascular and intravascular protein is 25:1, indicating that a total increment of 25 gm. of protein is required to increase plasma proteins by only 1 gm.<sup>28</sup> If this ratio were 10 in nephrotic patients, it is evident that 300 gm. of plasma protein must be given to increase the plasma protein concentration by 1 gm. per 100 cc. Even when adequate protein is furnished, however, repletion appears impossible in many patients. Moreover, it cannot be explained why endogenous protein synthesis should not be sufficiently effective to make more than 5 to 10 gm. of plasma protein daily in excess of metabolic needs when adequate dietary protein and a high intravenous protein intake are assured.

More direct evidence that a disturbance of nitrogen metabolism occurs is found in the behavior of the amino acid level in certain cases. Farr and MacFadyen<sup>29</sup> have observed a chronic reduction in the plasma amino acid concentration (ninhydrin method), which is accentuated prior to and during the "nephrotic crisis" in children with the nephrotic

syndrome. These episodes are characterized clinically by fever and abdominal pain occurring in association with a peritonitis for which, in many cases, there is no demonstrable infectious cause. Administration of amino acids parenterally is believed to have reduced the mortality of crisis.<sup>30</sup> Farr<sup>29</sup> thinks that the low level of amino acids may betoken "toxic destruction" of proteins since it is associated with a negative nitrogen balance and excessive nitrogen urinary loss. A similar hypoaminoacidemia has been observed in normal persons<sup>31</sup> during various infectious diseases and after trauma or operation. It is interesting that in these situations it is also attended by nitrogen loss and evidence of "toxic" proteinolysis. These phenomena cannot be explained at present, but it is possible that the patient with the nephrotic syndrome suffers continuously a similar defect in nitrogen metabolism that interferes with protein production.

It is of interest that dietary protein restriction coupled with plasmapheresis in dogs results in a marked hypoproteinemia characterized like the nephrotic syndrome by a marked decrease in the albumin fraction.<sup>32</sup> The maintenance of the plasma globulin concentration despite equivalent loss probably indicates more efficient replacement. It seems not unlikely that the failure of plasma globulin to fall in nephrosis in the presence of a depleted protein pool may likewise imply continued normal globulin synthesis and whatever defect there may be must concern albumin synthesis directly.

The principal site of albumin manufacture is believed to be the liver.<sup>33</sup> Few studies of liver function have been made during the nephrotic syndrome. Lytle et al.<sup>34</sup> found that nephrotic patients removed injected amino acids from the blood as readily as normal persons, whereas children with liver disease failed to do so. Moreover, Kirk<sup>35</sup> has shown that deamination of glycine proceeds normally in this disease. Galactose and bromsulphalein removal have been observed to be normal or occasionally only slightly impaired in other patients.<sup>36</sup> It is possible that these discrete activities are undisturbed even though hepatic protein synthesis is seriously deranged.

Since nephrotic patients appear to secrete little sulfur relative to nitrogen, it has been suggested that "deposit" protein<sup>37</sup> — characterized by a low sulfur content, presumably in the intracellular compartment of the protein pool — is chiefly concerned in urinary protein loss. Grabfield<sup>38</sup> considers a defect in the intermediary sulfur metabolism to be essential to the pathogenesis of the nephrotic syndrome. However, his work is based upon the total nitrogen and sulfur content of the urine. Hence it is possible that excessive excretion of nonprotein nitrogen is the cause for the observed reduction in nitrogen-sulfur ratio rather than a truly low nitrogen-sulfur ratio of urinary protein. Studies of nitrogen and sulfur metabolism with radioactive tracers

in the nephrotic syndrome are awaited with great interest

Epstein<sup>97</sup> has called attention to the possibility that a disorder of thyroid activity is involved, since the basal metabolic rate is frequently reduced. It is now generally believed, however, that this finding is of questionable significance. Edema<sup>98</sup> and the state of quasistarvation<sup>85</sup> may suffice to reduce the basal metabolism. Treatment with thyroid extract and thyroxin has proved disappointing.<sup>14, 85, 99</sup>

Insufficient evidence is at hand to prove conclusively that a faulty protein metabolism, particularly in plasma albumin synthesis, is in part responsible for hypoproteinemia. The irregularity of protein production and excretion in different patients, the failure to replace protein despite adequate and proper nitrogen supply and the signs of "toxic" protein destruction, including hypoaminoacidemia and negative nitrogen balance, seem to indicate this possibility. Nonetheless, protein loss in the urine is probably of the greatest importance since it appears to be essential to the development and maintenance of a low concentration of protein in the blood.

### EDEMA

From the standpoint of the patient, edema is the most distressing and disabling manifestation of the nephrotic syndrome. The distribution of subcutaneous fluid appears to be governed by gravity and tissue tension. Burch<sup>100, 101</sup> has shown that the predilection for the eyelids (particularly the lower lid) may be attributed to the low tissue pressure and the high distensibility of the skin in this area. Failure of lymphatic drainage when the eyelids are motionless and not blinking, as during sleep and during recumbency, explain the tendency for edema fluid to accumulate about the eyelids during the night. The genitalia and loose abdominal wall of many multiparas present similar characteristics and are often excessively edematous. This fluid may be under considerable pressure since the skin over the lower extremities may become shiny white and quite taut, often cracking and splitting under the strain. Edema fluid drains profusely through such breaks in the skin, and secondary infection, especially dangerous in these patients, may follow. Great discomfort may result from the restriction of movement. Pleural effusion or ascites often reduces the vital capacity greatly, and acute pulmonary edema occasionally appears. Localized edema of the glottis may prove rapidly fatal. Edema of the gastrointestinal tract<sup>102</sup> may account for radiologic evidence of delayed gastric emptying time and decreased motility of the small intestine.

The pathogenesis of nephrotic edema is not yet settled. Many discussions of this question fail to consider it in its entirety. Importance is attached, on the one hand, to the plasma protein concentration in relation to the osmotic pressure acting across

capillary membranes throughout the body as a determinant of the volume of interstitial fluid and, on the other, to renal activity in excreting or retaining water and electrolytes. Obviously, both factors are interrelated and interdependent. Neither should be stressed unduly to the exclusion of the other.

There is little doubt that a lowered plasma protein concentration results in the formation of edema.<sup>17, 103, 104</sup> Leiter<sup>105</sup> and others<sup>106, 107</sup> have proved conclusively that the removal of plasma proteins and low-protein diets lead to persistent hypoproteinemia and the development of edema in experimental animals. Starling's<sup>108</sup> hypothesis that the distribution of extracellular fluid is dictated by balanced transcapillary pressures — plasma oncotic pressure and tissue tension opposed to interstitial fluid oncotic pressure and capillary blood pressure — has been applied in explaining this phenomenon, in particular by Epstein,<sup>6</sup> who is largely responsible for the following viewpoint. Other things being equal, a reduction in plasma protein concentration connotes reduction in plasma oncotic pressure. This is even more likely in the nephrotic syndrome, in which the proteins of greatest osmotic activity are specifically withdrawn from the blood.<sup>109</sup> Moreover, many measurements of plasma osmotic pressure<sup>110-112</sup> reveal far greater diminution in the nephrotic patient than can be accounted for on the basis of the technical errors of the relatively crude methods thus far employed. Hence it may be presumed that the fall in oncotic pressure leads to increased filtration of water and diffusible solutes into the interstitial spaces, with an expansion of extracellular extravascular water volume and the formation of edema. The factors concerned in effecting a new equilibrium of the transcapillary forces are not easily discerned. Possibly, filtration in excess of reabsorption continues until an increment in tissue tension corrects the deficit in oncotic pressure.

According to this hypothesis the movement of fluid into the tissue spaces must occur at the expense of the plasma volume. The published figures for plasma volumes are conflicting.<sup>113-117</sup> In part, this may be attributed to errors introduced by lipidemia in various dye-dilution technics.<sup>37</sup> And in part it appears to be a result of a true variability in plasma volume. In accord with theory, plasma volume appears to be reduced in most cases. The most reliable studies, based upon measurements with carbon monoxide, indicate that the reduction of plasma volume is much less when anemia is a complicating factor. With diuresis, the plasma volume rises above normal in such cases, accounting, perhaps, for divergent observations.

Epstein's hypothesis is weakened considerably by observations that diuresis and loss of edema may occur in the absence of any detectable change in plasma protein concentration.<sup>118</sup> Plasma osmotic pressure may even fall. Similarly, in hunger edema, which resembles nephrotic edema in many respects,

the extracellular water volume may expand or contract without reference to protein concentration,<sup>119</sup> though it is claimed that osmotic-pressure changes are of chief importance.<sup>120</sup> Here, again, attention has been focused upon possible changes in the peripheral circulation. Keys<sup>119</sup> suggests that the capillary wall is in a state of 'dynamic non-equilibrium,' an assertion that is somewhat difficult to understand. Increased capillary permeability would increase effective filtration pressure across capillary walls and lead to edema formation. However, evidence that this occurs is unsatisfactory. The edema fluid and transudates contain very little protein, usually less than 0.5 per cent.<sup>121</sup> On the other hand, Luetscher<sup>87</sup> has found that injected albumin rapidly disappears from the blood, and Lange and his co-workers<sup>122</sup> claim that fluorescein bound to protein passes easily into the edema fluid. These observations require critical testing before they can be accurately evaluated. A third of the osmotic activity of plasma proteins depends upon their electrical charge and the resulting unequal distribution of diffusible ions on each side of the capillary membrane (the Donnan equilibrium).<sup>123</sup> A change in this characteristic, thus far not detected, may be a factor in determining equilibrium conditions in the capillaries and the distribution of extracellular water. Perhaps alterations in the capillary wall are influential in affecting this factor. Changes in over-all tissue tension and capillary pressure cannot be appraised with accuracy by the methods at present available.

Moreover, the use of albumin concentrates to repair the deficit in plasma albumin has proved rather disappointing.<sup>124, 125, 126</sup> Diuresis and mobilization of edema may occur in some cases, but the effect is often limited and unimportant. Marked increases in plasma volume may prove detrimental and prevent theoretically appropriate therapy, a development that would not be expected if reduced protein concentration were the sole important defect.

Opposed to the view that changes in the blood or at the periphery have primacy in determining the volume of extravascular fluid is the belief that renal dysfunction in the disposal of water and electrolytes is chiefly concerned. Certainly retention of water by the kidneys is required and does occur. One school of thought posits a specific fault in renal excretion of sodium.<sup>127, 128, 129</sup> This claim is now supported by a considerable body of evidence, but it has been clearly proved that the nephrotic patient handles sodium in a manner that differs quantitatively rather than qualitatively from the normal.<sup>130</sup> Indeed, the normal kidney, in the face of a water and sodium deficit, acts like the nephrotic kidney. Hence the nephrotic patient appears to be in a state of quasis dehydration, which might be explained by diversion of water and electrolytes from the plasma into the interstitium. In addition, there

are disturbances of renal function that may contribute positively. The glomerulotubular imbalance, described above, might be expected to predispose to retention by enhancing water and salt reabsorption in excess of the body need. Diuresis, either spontaneous or induced by intravenous injection of salt-poor human plasma albumin concentrates, has been observed to occur in association with an increase in glomerular filtration rate.<sup>38, 87, 131, 132</sup> The resulting reversal of the imbalance should be important in the explanation of the increased output of urine. The possibility that increased formation of antidiuretic hormone by the posterior pituitary is responsible in part for the water retention has been suggested by the appearance of antidiuretic substances in the urine.<sup>127</sup> There is no evidence that the increased tubular reabsorption of sodium is a result of adrenal cortical dysfunction.

The alleviation of the nephrotic syndrome during various infectious diseases has frequently been observed.<sup>129-130</sup> Clement<sup>125</sup> has described regression of edema in response to the pyrogenic reaction following administration of typhoid vaccine, and deliberate infection with measles has been suggested as one means of treating the disorder.<sup>129</sup> Unfortunately, the effect of fever cannot always be predicted. In many patients, it proves definitely detrimental, inducing hematuria and further accumulation of edema. Moreover, patients with the nephrotic syndrome are peculiarly lacking in resistance, usually dying as the result of some intercurrent infection. Hence, the pyrogenic reaction must be condemned as a therapy, but it is of great interest in connection with the problem of the pathogenesis of nephrotic edema. Fever gives rise to striking changes in the renal and peripheral circulations. The cardiac output rises, and blood flow through the kidney and skin increases, apparently as a result of vasodilation. How these changes are related to the withdrawal of tissue fluid and diuresis is unknown, but they indicate that hemodynamic factors play an important role.

It is evident that knowledge of nephrotic edema is fragmentary. Many unassailable facts are at hand, but they cannot be fitted as yet into any satisfactory theory. Probably several variables are involved. The accumulation of fluid in the tissue spaces undoubtedly denotes an imbalance of transcapillary pressures and simultaneous water and electrolyte retention by the kidney. Mobilization of edema requires an adjustment in the periphery to promote the flow of fluid into the blood and a change in renal function to permit its excretion. Unilateral activity thus appears unlikely, but the fundamental activities in the peripheral vascular bed and the kidney are obscure.

#### LIPIDEMIA

One of the most puzzling manifestations of the nephrotic syndrome is the disturbance of fat

metabolism that gives rise to hypercholesterolemia and hyperlipemia. The elevated concentration of fatty materials may render the plasma opaque and milky in appearance, and greasy in consistence. There is a tendency for the fat to separate slightly on standing, and part of it may be removed by centrifugation, but a considerable quantity appears to be loosely attached to protein or to serve as a coating of protein aggregates,<sup>63, 131</sup> so that complete physical separation may be impossible by ordinary means. Cholesterol is a relatively insoluble substance, and yet 1 or 2 gm may be carried in solution in each 100 mm of nephrotic plasma. Such quantities cannot be dissolved in normal plasma, but even larger amounts can be held in solution in the nephrotic plasma.<sup>132</sup>

No clinical abnormality can be definitely ascribed to lipidemia. Certainly, atherosclerosis occurs more frequently among nephrotic patients than in normal persons of the same age.<sup>133</sup> It is in children with this disorder that one sees the most advanced forms of childhood arteriosclerosis. There appears to be a relatively constant coincidental, but by no means obligatory, relation to hypoproteinemia and edema. When edema clears, the plasma lipids tend to return to normal levels, and if edema continues to be evident, lipidemia may persist even though uremia develops.<sup>134</sup>

Plasma cholesterol is always elevated. Levels as high as 2.0 and 2.3 gm per 100 cc have been observed. All the other lipid fractions are likewise increased. Cholesterol esters appear to rise in most patients to the same extent as free cholesterol.<sup>86</sup> Peters and Man<sup>135</sup> found that the phospholipids (lecithin, the cephalins and other phosphorus-containing lipids) parallel cholesterol, whereas Thomas<sup>136</sup> observed a somewhat closer relation between lipid phosphorus and the total lipid content of the plasma. The neutral fats are always increased, and it has been observed that they tend to make up a larger fraction (as much as half) of the total lipids as the disease advances.

The fat content of the diet appears to have little influence upon the plasma composition. Hiller et al<sup>137</sup> and others<sup>138</sup> observed slightly greater increments in the plasma fatty acid and lecithin content after fat ingestion than in normal subjects or nephritic patients, but it appears that nephrotic patients can burn fats as efficiently as normal persons, since the respiratory quotient decreases in a normal manner when fat makes up the greater portion of the caloric intake.

The causes of lipidemia in nephrosis are quite obscure. In large part this is a result of the confused state of knowledge regarding normal fat metabolism. Since nephrotic patients appear to absorb and utilize dietary fat in a normal manner it has been suggested that lipidemia represents a failure of the processes of fat removal from the blood into storage sites.<sup>137</sup> Contrariwise, Thannhauser<sup>139</sup> claims that

lipidemia is due to enhanced mobilization of fat from the body stores. There is no evidence in support of either hypothesis. Since wasting of the tissues is prominent, lipidemia has been likened to that occurring in starvation, but in chronic malnutrition the cholesterol content of the plasma is usually depressed.<sup>85</sup> The possibility that a disorder of the thyroid gland is involved has likewise been considered<sup>140</sup> and found wanting, since there is no response to specific therapy and reductions in the basal metabolic rate may be apparent rather than real owing to a failure to use "ideal" body weights in calculations.<sup>141</sup> Heymann and Clark<sup>142</sup> and Winkler and his co-workers<sup>143</sup> have induced lipidemia in animals by bilateral nephrectomy and ligation of the ureters. Lipidemia also develops after nephrotoxic nephritis<sup>144</sup> and subtotal nephrectomy.<sup>145</sup> The cause of this phenomenon is unknown, but it does not seem to have any relation to the problem in nephrosis, in which renal function is usually relatively unimpaired. It appears that lipidemia must be considered a phenomenon connected in some way as yet unknown with the hypoproteinemia and edema of the nephrotic syndrome. Little light has been thrown upon this question by the experimental production of hypoproteinemia in animals. In this situation the development of lipidemia is apparently attributable to hepatic insufficiency,<sup>146</sup> but in the nephrotic syndrome, hepatic function appears to be normal.

\* \* \*

As a rule the nephrotic syndrome is distinctive, presenting each of the specific disorders discussed at length above. It should be emphasized, however, that it may be complicated by other independent disturbances, such as congestive heart failure, uremia and hypertensive heart disease. Extraneous manifestations that mask or distort the usual clinical and physiologic pattern may thus be introduced. Finally, the syndrome itself presents a shifting and variable course. The most striking clinical phenomenon, edema, may be minimal and even absent from time to time. Proteinuria, hypoproteinemia and lipidemia are fundamental derangements, and so long as they persist the nephrotic syndrome may be considered to be present. This concept is important in the interpretation of therapeutic effects, since transient elimination of edema cannot be considered as evidence for the curative power of any agent.

Another confusing aspect of the nephrotic syndrome is the diversity of its causes. The typical complex of symptoms and signs may develop during syphilis and clear completely in response to antibiotic or arsenical therapy. Chronic diffuse glomerulonephritis, intercapillary glomerulosclerosis, amyloid disease and other disorders give rise to the same clinical picture. Each of these may be distinguished only by the characteristic renal lesion

or clinical course, or both. In only one disorder, lipid, "genuine" or chronic nephrosis, is there no anatomic change in the kidney. Since even in this condition proteinuria and other manifestations appear to depend upon an abnormality of glomerular membranes, lipid nephrosis may also be primarily a renal disease.

In any case, the nephrotic syndrome can be profitably viewed as a discrete entity. As such it remains an unsolved riddle. Secondary infection, which was formerly devastating in these patients, can now be combated with powerful chemotherapeutic agents, but specific therapy is altogether lacking. It can only be hoped that the use of newer methods of study in the clarification of the metabolic, hemodynamic and renal function disturbances, of which the available evidence is indicative rather than demonstrable, may yield a clue to the means of effective treatment.

### CASE 34081

#### PRESENTATION OF CASE

A forty-nine-year-old man entered the hospital because of difficulty in urination.

For two months he had frequency (ten times during the day and five times at night). This was associated with weakness and hesitancy of the stream. There was no dysuria, gross hematuria, back pain, feverishness or vomiting. One week before entry he had an attack of dyspnea, wheezing and cough, and he developed conjunctival and palpebral hemorrhages. The blood pressure was 120 systolic, 80 diastolic. The legs became edematous.

Physical examination revealed a pale drowsy man. The face was puffy, and there were conjunctival and palpebral hemorrhages. The eye grounds revealed flame-shaped hemorrhages, narrow arteries and blurring of the disk margins. The neck veins were distended and pulsating. There was an apical systolic murmur. In the abdomen there was a fluid-filled, tense, nontender mass extending upward from the pelvis to the level of the umbilicus. Rectal examination revealed tender external hemorrhoids and a questionably enlarged prostate. The legs and feet were edematous.

The temperature was 99°F, the pulse 88, and the respirations 16. The blood pressure was 175 systolic, 90 diastolic.

Examination of the blood disclosed a hemoglobin of 5 gm and a white-cell count of 7300. The non-

protein nitrogen was 200 mg, the calcium 6.8 mg and the phosphorus 8.2 mg per 100 cc, the alkaline phosphatase was 30 units, and the carbon dioxide was 10.6 milliequiv per liter. The prothrombin time was 18 seconds (control, 17 seconds). Repeated examinations of the urine gave a reaction of pH 6.0 to 7.0, with a specific gravity of 1.008 to 1.014, and a + to ++++ test for albumin. The sediment showed many red cells and on one occasion 20 to 30 white cells per high-power field. Cultures grew colonies of *Staphylococcus aureus* and colon bacilli.

An electrocardiogram showed digitalis effect only. An x-ray film of the chest revealed basal congestion of the lungs and some left ventricular hypertrophy. A plain film of the abdomen was normal.

The patient was catheterized in the Emergency Ward, and 750 cc of clear urine was removed. A few hours later, after several unsuccessful attempts to pass a No. 18 catheter, a No. 20 Foley catheter was passed without difficulty, and 1000 cc of clear urine removed. There was a good deal of subsequent bleeding into the bladder, and clots were removed by irrigations as required. He was digitalized and given resuspended red cells in 10 per cent dextrose in water. Fluids were forced to 4000 cc a day. The palpebral hemorrhage and edema gradually subsided. After a few days the indwelling catheter became very painful. He began to vomit, and fluids were then pushed intravenously and by proctoclysis. The uremia and acidosis increased. Repeated nonprotein nitrogen estimations were 175, 250, 210 and 280 mg per 100 cc, with corresponding carbon dioxide estimations of 10.6, 14.7, 13.4 and 17.5 milliequiv per liter. He died on the tenth hospital day.

#### DIFFERENTIAL DIAGNOSIS

DR FLETCHER H COLBY: May we see the x-ray films?

DR STANLEY M WYMAN: The heart shows enlargement, chiefly of the left ventricle. The aorta is unusually tortuous for a man of this age. The appearance suggests hypertension. There is an

area of ill defined, hazy density in the middle thirds of both lung fields, with slight accentuation of the basilar markings. No unusual soft-tissue masses are visible in the film of the abdomen, and there are no unusual areas of calcification.

DR COLBY Can you make out the renal outlines at all?

DR WYMAN I cannot make them out with certainty.

DR COLBY You cannot say whether or not they are enlarged?

DR WYMAN Not with enough certainty to rely on. My guess is that they may be slightly small.

DR COLBY The fact that a large catheter passed more easily than a small one is of no great significance—it is not unusual for a patient to have enough spasm of the sphincter muscles for that to happen. The subsequent bleeding into the bladder is not unusual. Any overdistended bladder may bleed in this manner when rapidly emptied.

When the patient entered the hospital he obviously was critically ill. All the signs and symptoms that we are given point to a lesion of the heart, as well as to some degree of urethral obstruction and certainly to severe renal damage. All these signs and symptoms may be integrated, although I cannot be certain.

Let us take up the obstructive feature first. The first possibility is some sort of congenital abnormality, which should have made itself evident before the age of forty-nine, however. Such lesions as congenital valves and congenital stricture of the urethra occur in young persons and become evident before this age. A stricture of the urethra can be eliminated by the fact that the patient had nothing in the past history to suggest it, and in the Emergency Ward he was easily catheterized. A catheter cannot be passed easily by a stricture of any severity.

Does a patient of forty-nine have benign hypertrophy of the prostate? He may. I recently operated on a man of forty-nine who had a definitely obstructed prostate with a stone in the bladder. I said, "You are young to have this." And he answered, "I know it, my brother is fifty, and last year he had his prostate operated on."

This man entered the hospital because of difficulty in urinating and with a past history of weakness and hesitancy of the stream. Certainly, prostatic hypertrophy is a definite possibility, and probably infection as well. The dyspnea, wheezing and cough, if not asthmatic (and apparently they were not), suggest cardiac disease. This is confirmed by the systolic murmur, distended neck veins, pulmonary congestion and left ventricular hypertrophy. We can therefore say that he had hypertensive heart disease. One thing that bothers me a good deal is the fact that the blood pressure was 120 systolic, 80 diastolic, and a week later 175 systolic, 90 diastolic. Is that correct?

DR EDWARD F. BLAND Not quite. On admission it was 200 systolic, 100 diastolic.

DR COLBY There was not the change from 120 to 175 systolic in a week?

DR BLAND A later reading was 165 systolic, 90 diastolic, and as the patient became sicker the pressure was lower.

DR FREDERICK C. GOETZ The blood pressure was 125 systolic, 70 diastolic, about a week before he entered the hospital, according to his doctor.

DR COLBY Was he pretty sick then?

DR GOETZ Yes, he was.

DR COLBY The general signs and symptoms are those of a marked degree of renal damage in a patient who was not able to concentrate urine above 1014. He had a low specific gravity of urine with albumin, a low serum calcium, a high phosphorus and marked anemia. The marked anemia must mean a disease of long standing. The hemoglobin was 5 gm. He also had eye signs and edema. It seems unlikely to me that such a degree of renal change in a man of forty-nine could have been associated with a hypertrophied prostate so that I think we have to look for the chief lesion in the kidneys.

What sort of lesion could it have been? The lack of pain in the past and the other symptoms seem to eliminate a certain number of renal lesions, such as hydronephrosis and calculus disease, and the obstructive lesions that affect the upper urinary tract. On the other hand this must have been a bilateral affair, and it seems to me that the most likely possibility is a severe degree of chronic pyelonephritis. This is borne out by the urinary findings, the low specific gravity, the edema, the obviously failing renal function, the eventual acidosis and death and uremia. He had a mixed infection, staphylococcus and colon bacilli in the urine, which is quite consistent with marked pyelonephritis. Acute pyelonephritis is much more apt to have only one organism.

One condition that I cannot rule out, although I have no evidence to favor it except a pair of kidneys that were failing, is bilateral polycystic disease, which is always a possibility. This man was at the age when polycystic disease is apt to make itself evident. There was nothing in the past history to suggest it, however, such as back pain, gradual rise in blood pressure and attacks of gross hematuria. But I cannot eliminate the possibility. That is why I asked particularly about the x-ray findings, to see if we could get any additional information from Dr. Wyman.

My diagnoses are therefore hypertensive heart disease, benign hypertrophy of the prostate and uremia due to pyelonephritis. The patient probably had a pair of lungs that showed quite a bit of edema.

DR TRACY B. MALLORY Can you add anything, Dr. Bland?

### CASE 34081

#### PRESENTATION OF CASE

A forty-nine-year-old man entered the hospital because of difficulty in urination.

For two months he had frequency (ten times during the day and five times at night). This was associated with weakness and hesitancy of the stream. There was no dysuria, gross hematuria, back pain, feverishness or vomiting. One week before entry he had an attack of dyspnea, wheezing and cough, and he developed conjunctival and palpebral hemorrhages. The blood pressure was 120 systolic, 80 diastolic. The legs became edematous.

Physical examination revealed a pale, drowsy man. The face was puffy, and there were conjunctival and palpebral hemorrhages. The eye grounds revealed flame-shaped hemorrhages, narrow arteries and blurring of the disk margins. The neck veins were distended and pulsating. There was an apical systolic murmur. In the abdomen there was a fluid-filled, tense, nontender mass extending upward from the pelvis to the level of the umbilicus. Rectal examination revealed tender external hemorrhoids and a questionably enlarged prostate. The legs and feet were edematous.

The temperature was 99°F, the pulse 88, and the respirations 16. The blood pressure was 175 systolic, 90 diastolic.

Examination of the blood disclosed a hemoglobin of 5 gm. and a white-cell count of 7300. The non-

protein nitrogen was 200 mg., the calcium 6.8 mg. and the phosphorus 8.2 mg. per 100 cc., the alkaline phosphatase was 3.0 units, and the carbon dioxide was 10.6 milliequiv. per liter. The prothrombin time was 18 seconds (control, 17 seconds). Repeated examinations of the urine gave a reaction of pH 6.0 to 7.0, with a specific gravity of 1.008 to 1.014, and a + to ++++ test for albumin. The sediment showed many red cells and on one occasion 20 to 30 white cells per high-power field. Cultures grew colonies of *Staphylococcus aureus* and colon bacilli.

An electrocardiogram showed digitalis effect only. An x-ray film of the chest revealed basal congestion of the lungs and some left ventricular hypertrophy. A plain film of the abdomen was normal.

The patient was catheterized in the Emergency Ward, and 750 cc. of clear urine was removed. A few hours later, after several unsuccessful attempts to pass a No. 18 catheter, a No. 20 Foley catheter was passed without difficulty, and 1000 cc. of clear urine removed. There was a good deal of subsequent bleeding into the bladder, and clots were removed by irrigations as required. He was digitalized and given resuspended red cells in 10 per cent dextrose in water. Fluids were forced to 4000 cc. a day. The palpebral hemorrhage and edema gradually subsided. After a few days the indwelling catheter became very painful. He began to vomit, and fluids were then pushed intravenously and by proctoclysis. The uremia and acidosis increased. Repeated nonprotein nitrogen estimations were 175, 250, 210 and 280 mg. per 100 cc., with corresponding carbon dioxide estimations of 10.6, 14.7, 13.4 and 17.5 milliequiv. per liter. He died on the tenth hospital day.

#### DIFFERENTIAL DIAGNOSIS

DR. FLETCHER H. COLBY: May we see the x-ray films?

DR. STANLEY M. WYMAN: The heart shows enlargement, chiefly of the left ventricle. The aorta is unusually tortuous for a man of this age. The appearance suggests hypertension. There is an

with a definitely smooth, normal-appearing mucosa over it, elevated above the surrounding mucosa by about 1 to 1.5 cm. There was very little distortion of the peristaltic wave. No ulcer was visible on its surface.

An operation was performed on the ninth hospital day.

#### DIFFERENTIAL DIAGNOSIS

**DR CLAUDE E. WELCH:** This is the record of a patient with a gastric lesion of an undetermined type with incidental hypertension, a mastectomy scar and varicose veins. The history of jaundice is very equivocal, and no further signs or symptoms later developed to implicate the biliary tract. The only other abnormal feature in the history or physical examination is that of slight edema of both lower legs. Since this patient was subjected to no further examination to clarify the cause of the edema, with the exception of one negative examination of the urine, I believe that we can dismiss this symptom as inconsequential.

We have, then, a history of anorexia that began ten months before admission. This was more or less persistent and was followed by epigastric pain at an indefinite date. The history is also very suggestive of an anemia due to blood loss that developed three months before entry.

The diagnosis of prepyloric ulceration was first made about six weeks prior to entry. It may be assumed that following this discovery the patient was treated for a peptic ulcer. However, the filling defect persisted, and was observed at a second examination six weeks later. This filling defect was again observed when the patient entered the hospital.

The presence of achlorhydria that was persistent despite the injection of histamine is of great importance, since nearly 50 per cent of the patients with this finding and a gastric ulceration are found on pathological examination of the resected specimens to have cancer of the stomach.

The x-ray and gastroscopic findings were as usual somewhat at variance. Both of them suggest a submucosal lesion on the lesser curvature in the antral area. However, the presence of ulceration that was noted three times on the x-ray examination was not observed by the gastroscopist. Under these circumstances and in this location, I favor the x-ray description and consider it definite that this patient had an ulcerating lesion. That it was associated with a submucosal mass is quite likely, but not nearly so important as the presence of the ulceration itself.

There are only a few diagnoses to be considered. The ulcer must have been a benign gastric ulcer, carcinoma or the tiny ulceration that is frequently found over pancreatic rests or spindle-cell tumors. The evidence of a submucosal mass could point to a spindle-cell tumor, a pancreatic rest or a tumor that is projecting into the wall of the stomach from

the lesser peritoneal cavity. In this location, of course, the most likely source is the pancreas. It will be noted that the ulceration appeared on x-ray study prior to the time that the larger filling defect first appeared. It could therefore have represented an extension of carcinoma into the submucosal area or even outside the stomach.

The salient features of a prepyloric lesion of short duration developing in a patient in the older age group, the ulceration being associated with complete achlorhydria and failing to heal under at least six weeks of medical treatment, all point to the diagnosis of carcinoma of the stomach rather than to benign ulcer or the rarer tumors mentioned above.

**DR MILFORD D. SCHULZ:** All films made of the stomach show a sharply delimited defect on the lesser-curvature side of the antrum, measuring only a few centimeters across. The mucosal pattern stops abruptly at the defect, which looks as though it is caused by a smooth mass projecting into the stomach lumen. I am not certain about the ulceration described—it may be just barium caught in a fold. If there is ulceration, it must be in a tumor mass, but whether the tumor is intraluminal or intramural is not certain, though from the films I should suspect the tumor to be intraluminal.

Incidentally, there is a small diverticulum of the duodenum lying just oast to the antral defect.

**DR EDWARD B. BENEDET:** It interests me that Dr. Welch should say that the x-ray and gastroscopic findings were "as usual" somewhat at variance. As a matter of fact, in the easy cases they usually agree, in the difficult ones they may not. In a review of 298 cases of gastric carcinoma, gastric ulcer, jejunal ulcer, gastritis, benign tumor, lymphoma, sarcoma, metastatic carcinoma and normal stomach studied by x-ray and gastroscopy and proved by pathological examination, it was demonstrated that the radiologist and gastroscopist agreed in more than half the cases.<sup>1,2</sup> It was also shown that, provided the gastroscopist obtains a good view of the lesion, his chances of reaching a correct diagnosis are greater than those of the radiologist. In this case the view was good, and there was no doubt in my mind that the lesion was submucosal. In my experience, nonulcerating submucosal tumors of the stomach have always been benign, with the exception of 1 case of carcinoma of the pancreas invading the stomach submucosally. Because of the vomiting, the proximity of the tumor to the pylorus and the possibility of cancer I felt that the lesion should be resected. If pathological study of the resected specimen demonstrates an ulcerating tumor, it shows how easy it is for the gastroscopist to miss an ulcer in or beyond a tumor. If, however, this proves to be a nonulcerating malignant submucosal tumor of the stomach, I believe it is exceptional. Whatever the pathological report, it is usually wise to

of biologic knowledge and medical treatment, have been clearly shown by Professor H J Muller,<sup>1, 2</sup> to produce deleterious hereditary mutations. The physician is interested in the welfare of the individual, but the scope of his activities and concerns must include the race if he is to avoid the reproach of the eugenicists that his efforts lead to the final injury of the race. In this, human beings are not exempt from the dangerous results of the advances of science in general.

What is of great importance both theoretically and practically is that a misleading dichotomy must now be discarded — namely, that hereditary and environmental agencies are separable in any complete sense. Germ plasma, the substances of ovum and sperm, is relatively stable, but that stability depends on a stable environment. The inner environment, such as the blood stream, is as necessary to the germ plasma as to the cells of other tissues and organs of the body. There is a vast experimental literature on this subject, including the influence of the vitamins, especially A and E, on the maturation and health of sperm and ovum, that is incontestable.<sup>3-12</sup>

Moreover, Mendelian heredity is fast becoming only a part of genetic knowledge. We are passing into a phase of great scientific advance, involving the physiology and biochemistry of the genes and of the cytoplasm of the gonads as well.<sup>13</sup> The nucleoproteins,<sup>14</sup> for example, are as basic in transmitting the qualities of hereditary nature as they are in the life history of the individual cell and of the body as a whole.

Of further practical importance is the fact that environmental forces can be so focused on the developing embryo as to produce what appears to be a mutation, the so-called phenocopy of Gold-

schmidt.<sup>15</sup> Recently, Wesselhoeft<sup>16</sup> pointed out that German measles, a relatively mild infection, produces an appalling amount of deficiency in the children of mothers who acquired the infection early in pregnancy. This brings to medical attention the extremely important question of the role of "blastophthoria," a term that means merely sick or injured germ plasma as the source of deficiency in human beings. This concept was introduced by Forel<sup>17</sup> and emphasized by Myerson<sup>18</sup> as a theoretic constitutional basis for mental disease, but the geneticists have rather loftily dismissed it as unimportant. Muller's work, which is the great climax of similarly directed investigations, shows that the germ plasma does not dwell in a sanctum sanctorum, but can be destroyed, injured and deviated from normal

functioning by the universe of penetrating forces in which it dwells.<sup>19</sup>

## TO THE FELLOWS OF THE MASSACHUSETTS MEDICAL SOCIETY

On behalf of the trustees I welcome to membership in the Boston Medical Library all of you who are not already numbered among its fellows.

The Boston Medical Library is one of the leading institutions of its kind in the country. On its shelves are over 200,000 volumes and its collection of periodicals in many languages is outstanding. We wish this great library to be at the service of every physician in Massachusetts, and the share of your increased membership dues that has been allocated to it will make such a goal possible.

We hope that you will show your interest in the Library by visiting it and making use of its facilities.

## MASSACHUSETTS MEDICAL SOCIETY

### TREASURER'S OFFICE

All members should be reminded that the proportion of the refund returned to each district society is based on the number of dues paid by March 1 in that district, and also that the names of members who have not paid their dues by March 1 are automatically removed from the mailing list of the *Journal* until such dues are paid. This year \$8000 is being returned to the district societies rather than \$4000 as heretofore.

ELIOT HUBBARD, JR., *Treasurer*

### DEATHS

CRUFF—Frederick E. Cruff, M.D. of Norwell died on January 18. He was in his fifty-third year.

Dr. Cruff received his degree from Harvard Medical School in 1920. He was a member of the Association of Military Surgeons.

His widow and a daughter survive.

HUNT—Ernest L. Hunt, M.D. of Worcester, died on January 17. He was in his seventy-first year.

Dr. Hunt received his degree from Harvard Medical School in 1902. He was surgeon-in-chief of Fairlawn Hospital and director of Worcester Health Department laboratories and was formerly associate medical examiner for Worcester County. He served as a medical officer in World War I. He was a member of the New England Surgical Society and the American Urological Association and a fellow of the American College of Surgeons and the American Medical Association.

His widow, three daughters, a son and nine grandchildren survive.

JONES—Raymond C. Jones, M.D. of Fitchburg died on December 2. He was in his sixty-seventh year.

Dr. Jones received his degree from University of Vermont College of Medicine in 1902.

His widow and a sister survive.

KING—Connie H. King, M.D. of Duxbury died on January 22. He was in his forty-first year.

Dr. King received his degree from University of Tennessee College of Medicine in 1929. He was assistant medical examiner for Plymouth County and chief aesthetist at Jordan Hospital, Plymouth.

His widow, a son, a daughter, two brothers and a sister survive.

McMILLAN—Archibald McMillan, M.D. of Athol died on January 16. He was in his seventy-sixth year.

Dr. McMillan received his degree from Bowdoin Medical School in 1904.

PENDOLA—Anthony S. Pendola, M.D. of Holyoke died on January 10. He was in his fifty-eighth year.

Dr. Pendola received his degree from Middlesex University School of Medicine in 1920. He was a member of the staffs of Providence and Holyoke hospitals and was assistant city physician.

His widow, three brothers and two sisters survive.

## POSTGRADUATE LECTURE COURSE

The third Postgraduate Lecture Course, which has been arranged by the Committee on Postgraduate Medical Education, Massachusetts Medical Society, in co-operation with the Massachusetts Department of Public Health, will begin on March 8. The meetings will be held at Sanders Theater in Memorial Hall, Harvard University, Cambridge. These lectures are designed for all physicians of Massachusetts and surrounding states, medical officers, hospital residents, interns, medical students and postgraduate students.

All those who plan to attend but have not enrolled should do so immediately by either returning the post card recently forwarded to all physicians in Massachusetts or addressing a post card or letter directly to Postgraduate Lecture Course Committee, Massachusetts Medical Society, 8 Fenway, Boston 15.

The detailed program for the course is as follows (no buffet suppers will be served this year)

**Monday March 8 EARLY DIAGNOSIS AND TREATMENT OF CANCER.** Chairmen: Charles C. Lund and Ira T. Nathan

5:55-6:00 OPENING REMARKS Edward P. Bagg, president, Massachusetts Medical Society

6:00-6:40 Cancer of the Oral Cavity William S. MacComb, attending surgeon, Memorial Hospital, New York City

6:40-7:05 Cancer of the Larynx and Pharynx. Leroy A. Schall, chief Oto-Laryngological Service, Massachusetts Eye and Ear Infirmary, professor of laryngology and otology, Harvard Medical School

7:05-7:35 Cancer of the Lung E. D. Churchill, chief West Surgical Service, Massachusetts General Hospital

7:35-8:05 Cancer of the Esophagus Richard H. Sweet, visiting surgeon, Massachusetts General Hospital, surgeon, Palmer Memorial Hospital, instructor in surgery, Harvard Medical School

8:05-8:30 Cancer of the Stomach Arthur W. Allen, chief East Surgical Service, Massachusetts General Hospital, lecturer in surgery, Harvard Medical School

8:30-9:00 Cancer of the Colon and Rectum Richard B. Cattell, surgeon, Lahey Clinic, New England Baptist Hospital and New England Deaconess Hospital

**Wednesday March 10 EARLY DIAGNOSIS AND TREATMENT OF CANCER.** Chairmen: Charles C. Lund and Ira T. Nathan

3:00-3:45 Cancer of the Breast—Diagnosis and Surgical Aspects C. D. Haagenboom, assistant professor of surgery, College of Physicians and Surgeons, Columbia University, New York City

3:45-4:30 Cancer of the Breast—Radiation Aspects M. Lenz, chief Radiological Department, Presbyterian Hospital, New York City, professor of clinical radiology, College of Physicians and Surgeons, Columbia University, New York City

4:30-5:15 Cancer of the Cervix—Early Diagnosis Paul Younge, visiting surgeon, Free Hospital for Women, Brookline

5:15-6:00 Cancer of the Cervix and Endometrium Joe V. Mengs, chief Gynecological Service, Massachusetts General Hospital, clinical professor of gynecology, Harvard Medical School

**Monday, March 15** **CARDIOVASCULAR DISEASES** Chairmen Paul D White and Louis Wolff

6 00-6 25 **Examination of the Patient with Heart Disease** Louis Wolff, associate in medicine, Harvard Medical School, visiting physician, Beth Israel Hospital, consultant in cardiology, Beth Israel Hospital

6 25-6 50 **Roentgenology — Its Value in Cardiac Diagnosis** Felix F Fleischner, director, X-ray Department, Beth Israel Hospital, instructor in radiology, Harvard Medical School and Tufts College Medical School

6 50-7 15 **Electrocardiography Today** Conger Williams, assistant in medicine, Harvard Medical School, consultant in diabetes, Boston Lying-in Hospital

7 15-7 30 **Intermission**

7 30-8 00 **Symptoms of Heart Disease** S A Levine, assistant professor of medicine, Harvard Medical School, physician, Peter Bent Brigham Hospital

8 00-8 30 **The Use of Digitalis** A S Freedberg, associate visiting physician, associate in medical research, Beth Israel Hospital, associate in medicine, Harvard Medical School

8 30-9 00 **Treatment of Myocardial Failure** Paul D White, clinical professor of medicine, Harvard Medical School, physician, Massachusetts General Hospital

**Wednesday, March 17** **EPIDEMIC DIARRHEA IN INFANTS** Chairmen Clement A Smith and Nathan B Talbot

3 00-3 30 **Present Concepts of Etiology** John F Enders, associate professor of bacteriology and immunology, Harvard Medical School, chief, Research Division of Infectious Diseases, Children's Hospital

3 30-4 00 **Epidemiologic Management** Clement A Smith, assistant professor of pediatrics, Harvard Medical School, chief, Infants' Hospital

4 00-4 30 **Clinical Management** Allan M Butler, professor of pediatrics, Harvard Medical School, chief, Children's Medical Service, Massachusetts General Hospital

4 30-6 00 **Open Forum** Drs Butler, Smith, Talbot and Enders

**Monday, March 22** **ARTHRITIS** Chairmen Theodore B Bayles and Charles L Short

6 00-6 20 **Classification of Joint Disease** Charles L Short, associate physician, Massachusetts General Hospital

6 20-6 50 **The Diagnostic Value of Synovial Fluid Examination** Marian W Ropes, assistant professor of medicine, Harvard Medical School, associate physician, Massachusetts General Hospital

6 50-7 20 **Rheumatoid Spondylitis Recognition and Treatment** J Sydney Stillman, assistant in medicine, Harvard Medical School, physician-in-chief, Robert Breck Brigham Hospital

7 20-7 30 **Intermission**

7 30-8 00 **Gout** Walter Bauer, associate professor of medicine, Harvard Medical School, physician, Massachusetts General Hospital

8 00-8 30 **Shoulder-Hand Syndromes** Theodore B Bayles, assistant in medicine, Harvard Medical School, visiting physician, Robert Breck Brigham Hospital, chief, Arthritis Clinic, Peter Bent Brigham Hospital

8 30-9 00 **Nonsurgical Orthopedic Care of Arthritic Joints** Theodore A Potter, instructor in orthopedic surgery, Boston University School of Medicine, visiting orthopedic surgeon, Robert Breck Brigham and Massachusetts Memorial Hospitals

**Wednesday, March 24** **INFECTIOUS DISEASES** Chairmen Maxwell Finland and Charles A Janeway

**PART I**

3 00-3 20 **Indications and Uses of Vaccines and Antisera** Geoffrey Edsall, director, Division of Biologic Laboratories, assistant professor of public-health bacteriology, Harvard School of Public Health

3 20-3 40 **Hemolytic-Streptococcus Infections** Louis Weinstein, assistant professor of medicine, Boston University School of Medicine, instructor in infectious diseases, Harvard Medical School, physician and chief-of-service, Haynes Memorial Hospital

3 40-4 00 **Rheumatic Fever** David Rutstein, visiting physician, Children's Hospital and House of the Good Samaritan, consultant in preventive medicine, Peter Bent Brigham Hospital and Massachusetts General Hospital, professor of preventive medicine, Harvard Medical School

4 00-4 15 **Discussion**

**PART II**

4 15-4 35 **Clinical Aspects of Virus Diseases** Conrad Wesselschoft, professor of clinical medicine, Boston University School of Medicine, professor of communicable diseases, Harvard Medical School and Harvard School of Public Health

4 35-4 55 **Newer Methods in the Diagnosis of Specific Virus Diseases** F Sargent Choccy, assistant professor of bacteriology, Harvard Medical School

4 55-5 00 **Discussion**

**PART III**

5 00-5 30 **The Diagnosis of Obscure Fever** Chester S Keefer, professor of medicine, Boston University School of Medicine, director, Evans Memorial, Massachusetts Memorial Hospitals

5 30-6 00 **Progress in Pulmonary Tuberculosis** Dr Donald S King, lecturer in medicine, Harvard Medical School, physician, Massachusetts General Hospital

**Monday, March 29** **NEUROLOGY** Chairmen Derek E Denny-Brown and Charles S Kubik

6 00-6 40 **The Place of Thymectomy in the Treatment of Myasthenia Gravis** Henry R Vicks, lecturer on neurology, Harvard Medical School, neurologist, Massachusetts General Hospital

6 50-7 30 **Clinical Varieties of Multiple Neuritis** Derek E Denny-Brown, James Jackson Putnam Professor of Neurology, Harvard Medical School, director, Neurological Unit, Boston City Hospital

7 40-8 20 **The Place of Penicillin in the Treatment of Neurosyphilis** Raymond D Adams, assistant professor of neurology, Harvard Medical School, lecturer in neurology, Tufts College Medical School, visiting neurologist and neuropathologist, Boston City Hospital

8 20-9 00 **Diagnosis of Spinal-Cord Compression** Charles S Kubik, chief, Neurological Service, Massachusetts General Hospital, professor of medicine, Harvard Medical School

**Wednesday, March 31** **DERMATOLOGY** Chairmen John G Downing and Jacob H Swartz

3 00-3 30 **Treatment of Bacterial, Virus and Parasitic Diseases of the Skin** Francis Thurmon, clinical professor of dermatology, Tufts College Medical School

3 30-4 00 **Treatment of Psoriasis, Seborrhea and Nutritional Diseases** Bernard Appel, clinical professor of dermatology, Tufts College Medical School

4 00-4 30 **Treatment of Fungus Diseases of the Skin** Jacob H Swartz, assistant professor of dermatology, Harvard Medical School and Postgraduate School

4 30-5 00 **Dermatologic Allergy, Including Drug Eruptions** G Marshall Crawford, acting head, Department of Dermatology, Harvard Medical School

5 00-5 30 **Cutaneous Manifestations of Systemic Diseases** John G Downing, professor of dermatology, Boston University School of Medicine and Tufts College Medical School

5 30-6 00 **Question Period**

**Monday April 5 ALLERGY** Chairmen Jeremiah E. Greene and Francis C. Lowell

6:00-6:45 **Allergy—Its Scope and Place in Medicine** Walter S. Burrage, assistant physician, Massachusetts General Hospital, physician New England Deaconess Hospital, assistant in medicine, Harvard Medical School

6:45-7:30 **The Treatment of Asthma with Drugs** Francis C. Lowell, associate professor of medicine, Boston University School of Medicine, chief, Allergy Clinic, Out Patient Department, Massachusetts Memorial Hospitals

7:30-7:40 **Intermission**

7:40-8:15 **Skin Tests and Injection Therapy in Hay Fever and Asthma** Jeremiah E. Greene, affiliated with Massachusetts General Hospital, Mt. Auburn Hospital, Newton-Wellesley Hospital and New England Baptist Hospital

8:15-9:00 **The Antihistaminic Drugs** Francis C. Lowell, associate professor of medicine, Boston University School of Medicine, chief of Allergy Clinic, Out Patient Department, Massachusetts Memorial Hospitals

**Wednesday April 7 OFFICE PROCEDURES IN DISEASES OF MOUTH, VAGINA AND RECTUM** Chairmen Walter B. Hoover, Roy E. Mabrey and Francis P. McCarthy

3:00-3:20 **Lesions of the Oral Mucosa** Francis P. McCarthy, professor of oral medicine, Tufts College Dental School, lecturer in dermatology and syphilology, Tufts College Medical School

3:20-3:40 **Lesions of the Hard Parts of the Oral Cavity** Joseph F. Volker, dean and professor of clinical dentistry, Tufts College Dental School

3:40-4:00 **Lesions of the Oropharynx** Walter B. Hoover, chief, Department of Nose and Throat, Lahey Clinic

4:00-4:10 **Intermission**

4:10-4:35 **The Vaginal Smear in the Diagnosis of Carcinoma of the Uterus** Howard Ulfelder, assistant in surgery, Massachusetts General Hospital

4:35-5:00 **Displacements of the Uterus** Louis E. Phaneuf, professor of gynecology, Tufts College Medical School, chief, Department of Gynecology, Carney Hospital

5:00-5:20 **Methods of Diagnosis of Anorectal Diseases** Roy E. Mabrey, assistant surgeon, Massachusetts General Hospital

5:20-5:40 **The Problem of Rectal Bleeding** Neil W. Swinton, surgeon, Lahey Clinic, New England Deaconess Hospital and New England Baptist Hospital

5:40-6:00 **Premalignant and Malignant Lesions of Rectum and Colon** E. Parker Hayden, chief, Proctologic Clinic and assistant visiting surgeon, Massachusetts General Hospital

**Monday, April 12 CLINICAL ROENTGENOLOGICAL, PATHOLOGICAL SESSION** Chairman Merrill C. Sosman (who will present the Case Reports)

6:00-7:00 **Bone Diseases** William T. Green, orthopedic surgeon, Peter Bent Brigham Hospital, visiting orthopedic surgeon, Children's Hospital, assistant professor of orthopedic surgery, Harvard Medical School, Sidney Farber, pathologist, Children's Hospital, assistant professor of pathology, Harvard Medical School

7:00-8:00 **Chest Diseases** Cutting B. Favour, associate in medicine, Harvard Medical School, associate in medicine, Peter Bent Brigham Hospital, and Alan Moritz, pathologist, Peter Bent Brigham Hospital, professor of legal medicine, Harvard Medical School

8:00-9:00 **Endocrine Problems** Lewis M. Hurstthal, director, Department of Medicine, Lahey Clinic, and S. Burt Wolbach, pathologist-in-chief, Children's Hospital, Shattuck Professor of Pathology, Harvard Medical School

**Wednesday April 14 GASTROENTEROLOGY** Chairmen Benjamin M. Banks and James A. Halsted

3:00-3:20 **Functional Gastrointestinal Disorders—Principles of Management** James A. Halsted, physician-in-chief, Faulkner Hospital

3:20-3:45 **The Role of the Internist in the Management of Chronic Ulcerative Colitis** Benjamin M. Banks, chief, Gastrointestinal Clinic and associate visiting physician, Beth Israel Hospital

3:45-4:10 **The Role of the Psychiatrist in the Management of Chronic Ulcerative Colitis** Erich Lindemann, psychiatrist, Massachusetts General Hospital

4:10-4:35 **The Role of the Surgeon in the Management of Chronic Ulcerative Colitis** Leland S. McKitt, visiting surgeon, Massachusetts General Hospital

4:35-4:45 **Intermission**

4:45-5:10 **The Differential Diagnosis of Dysphagia** Seymour Gray, senior associate in medicine, Peter Bent Brigham Hospital

5:10-5:35 **Surgical Treatment of Carcinoma of the Esophagus and Cardiac End of the Stomach** Richard H. Sweet, visiting surgeon, Massachusetts General Hospital

5:35-6:00 **Discussion**

**Tuesday, April 20 (Note change from Monday, April 19) ENDOCRINE AND DIABETES.** Chairmen Frank N. Allan and Joseph C. Aub

6:00-6:30 **Treatment of Diabetic Coma** Allan M. Butler, professor of pediatrics, Harvard Medical School

6:30-7:00 **Endocrine Complications of Diabetes** Frank N. Allan, associate director, Medical Department, Lahey Clinic

7:00-7:30 **Sex Hormones in Growth** Joseph C. Aub, professor of research in medicine, Harvard Medical School

7:30-8:00 **Menstrual Disorders** John Rock, clinical professor of gynecology, Harvard Medical School

8:00-8:30 **The Theoretical Background of Therapy of the Thyroid** J. H. Means, Jackson Professor of Clinical Medicine, Harvard Medical School

8:30-9:00 **Studies on Acromegaly** Fuller Albright, associate professor of medicine, Harvard Medical School

**Wednesday, April 21 PSYCHIATRY** Chairmen Robert E. Fleming and Harry C. Solomon

3:00-3:30 **Psychiatric Procedure and Technique** Harry C. Solomon, professor of psychiatry, Harvard Medical School

3:30-4:00 **Adjustment Problems of the Pre-school Child** Marian C. Putnam, director, The James Jackson Putnam Children's Center

4:00-4:30 **Psychiatric Problems of the Adolescent** George E. Gardner, executive director, Judge Baker Guidance Center

4:30-5:00 **Psychiatric Problems of Young Men** Gaylord P. Coon, psychiatrist, Department of Hygiene, Harvard University

5:00-6:00 **Psychiatric Aspects of Acute Grief** Erich Lindemann, psychiatrist, Massachusetts General Hospital

**Monday April 26 CONVULSIVE SEIZURES.** Chairmen William G. Lennox and Maxwell E. MacDonald

6:00-6:30 **Differential Diagnosis and Etiology** William G. Lennox, visiting neurologist, Boston City Hospital, assistant professor of neurology, Harvard Medical School

6:30-7:10 **Neurosurgical Considerations and Treatment** Wilder Penfield, Montreal, Canada, professor of neurology and neurosurgery, McGill University, Montreal

7 10-7 50 **Medical and Drug Therapy** H Houston Merritt, professor of clinical neurology, Columbia University College of Physicians and Surgeons, New York City

7 50-8 20 **Psychological and Social Problems and Treatment** Maxwell E Macdonald, professor of neurology, Harvard Medical School, senior neurologist, Boston City Hospital

8 20-9 00 **Question Period**

**Wednesday, April 28 BLOOD DISEASES** Chairmen William Dameshek and John W Norcross

#### PART I THE DIAGNOSIS AND TREATMENT OF HEMORRHAGIC DISEASE

3 00-3 30 **Diagnostic Tests** Jacob Neber, assistant in hematology, Joseph H Pratt Diagnostic Hospital

3 30-4 00 **The Purpuras** Charles S Davidson, associate in medicine, Harvard Medical School, junior visiting physician, Boston City Hospital

4 00-4 30 **Hemophilia** Benjamin Alexander, instructor in medicine, Harvard Medical School, visiting physician and associate in medical research, Beth Israel Hospital

#### PART II SYMPOSIUM ON TREATMENT

4 30-5 00 **Treatment of Anemia** Donat Cyr, assistant hematologist, Department of Medicine, Lahey Clinic

5 00-5 30 **Chemotherapy of Leukemia and Lymphoma** William Dameshek, professor of clinical medicine, Tufts College Medical School, consultant in hematology and visiting physician, Joseph H Pratt Diagnostic Hospital

5 30-6 00 **Splenectomy in Blood Disorders** John W Norcross, hematologist, Department of Medicine, Lahey Clinic

**Monday, May 3 GENITOURINARY DISEASE** Chairmen J Hartwell Harrison and George C Prather

6 00-6 30 **Hematuria Significance and Management** J Hartwell Harrison, senior associate in genitourinary surgery, Peter Bent Brigham Hospital, associate professor of genitourinary surgery, Harvard Medical School

6 35-7 00 **Pain Interpretation relative to genitourinary causes** George C Prather, visiting neurologic surgeon, Boston City Hospital, instructor in genitourinary surgery, Harvard Medical School

7 10-7 40 **Streptomycin in the Treatment of Non-tuberculous Bacillary Urinary Infections** Maxwell Finland, physician-in-chief, Fourth Medical Service, Boston City Hospital, assistant professor in medicine, Harvard Medical School

7 45-8 15 **The Diagnosis and Treatment of Cancer of the Prostate** Wyland F Leadbetter, assistant professor in genitourinary surgery, Harvard Medical School, clinical professor of urology, Tufts College Medical School, associate visiting urologist, Massachusetts General Hospital

8 20-8 50 **Present Outlook in Carcinoma of the Bladder** Roger C Graves, clinical professor of urology, Tufts College Medical School, urologist-in-chief, Carney Hospital

**Wednesday, May 5 OBSTETRICS** Chairmen Duncan E Reid and Benjamin Tenney, Jr

#### PART I DIABETES MELLITUS IN PREGNANCY

3 00-3 25 **Medical Treatment** David Hurwitz, assistant instructor in medicine, Harvard Medical School, consultant in diabetes, Boston Lying-in Hospital

3 25-3 45 **Endocrinological Treatment** Olive Smith, Ph D, director, Fearing Research Laboratory, Free Hospital for Women

3 45-4 00 **Question Period**

#### PART II HEART DISEASE IN PREGNANCY

##### A TWENTY-FIVE-YEAR REVIEW

4 00-4 25 **Treatment** Burton Hamilton, clinical associate, Thorndike Memorial Laboratory, Boston City Hospital, instructor, graduate courses, Harvard Medical School

4 25-4 30 **Question Period**

#### PART III HYPERTENSION IN PREGNANCY

4 30-4 55 **Medical Aspects** Lewis Dexter, associate in medicine, Peter Bent Brigham Hospital and Harvard Medical School

4 55-5 15 **Obstetrical Aspects** Benjamin Tenney, associate professor of obstetrics, Boston University School of Medicine, assistant obstetrician, Massachusetts General Hospital

5 15-5 30 **Question Period**

#### PART IV VAGINAL BLEEDING IN LAST TRIMESTER OF PREGNANCY

5 30-5 45 **Clinical Aspects** H Bristol Nelson, senior obstetrician, Boston Lying-in Hospital, professor of gynecology and obstetrics, Harvard Medical School

5 45-5 55 **Pathological Aspects** Arthur T Hertig, assistant professor of obstetrics and assistant professor of pathology, Harvard Medical School, pathologist, Free Hospital for Women, obstetrician, Out-Patient Department, Boston Lying-in Hospital

5 55-6 00 **Question Period**

## MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

### REVIEW OF COMMUNICABLE DISEASES IN 1947

The year 1947 was very favorable regarding the general prevalence of communicable diseases. The total number of cases reported to the Department—76,469—was the lowest reported since 1916, the lowest figure in recent years being 78,089 cases in 1938. The low figure for 1947, however, can be attributed largely to the low prevalence of some of the less serious diseases of childhood. Both measles and German measles were much below normal. Scarlet fever reached the lowest level since 1905. On the other hand, the record for 1947 would have been still lower had not chicken pox reached the second highest figure since the disease was reportable, and mumps and whooping cough maintained about the normal prevalence.

Meningococcal meningitis, lobar pneumonia and typhoid fever were at very low levels, and gonorrhea and syphilis showed some decline. Bacillary dysentery, poliomyelitis and salmonellosis were at about the normal prevalence. On the other hand, diphtheria, tularemia, trichinosis and undulant fever all showed an increase.

Diphtheria continues to be a trying problem. It was hoped that the increased emphasis on immunization programs would bring the prevalence down, but more cases were reported this year than in 1946, which itself was the highest year since 1934.

On the other hand, not a single case of smallpox was reported, marking the fifteenth year since the disease was prevalent in the State. Typhoid fever dropped to the second lowest level since reporting began.

DISEASE	1947	1946	SEVEN YEAR MEDIAN
Actinomycoma	1	3	3
Anthrax	2	3	3
Chancroid	31	19	20*
Chicken pox	18,791	11,912	11,912

## MISCELLANY

### APPOINTMENT OF MANFRED BOWDITCH

Manfred Bowditch, formerly field director of the Saranac Laboratory and director of the Division of Occupational Hygiene of the Department of Labor and Industries of the Commonwealth of Massachusetts, has been appointed director of health and safety of the Lead Industries Association. He will make his office at the Association's headquarters, 420 Lexington Avenue, New York City.

### NATIONAL COMMITTEE FOR MENTAL HYGIENE

Dr. Arthur H. Ruggles, former superintendent of the Butler State Hospital, Providence, Rhode Island, has been elected president of the National Committee for Mental Hygiene. Dr. Ruggles, who has been the superintendent of Butler Hospital since 1922, is president of the Emma Pendleton Bradley Home, Providence, and a trustee of Dartmouth College. He is consultant in mental hygiene in the Department of University Health and lecturer in psychiatry at Yale University, a member of the advisory council on research in nervous and mental diseases and consultant, United States Public Health Service, and a member of the advisory council of the Department of Social Welfare of Rhode Island. Dr. Ruggles is a former president of the American Psychiatric Association and of the New England Society for Psychiatry.

### CANCER

A new journal, *Cancer*, sponsored by the American Cancer Society, will make its appearance this spring. Every phase of the cancer problem will be covered, with major emphasis on clinical aspects. Dr. Fred W. Stewart, of Memorial Hospital, New York City, will be the editor-in-chief, assisted by an editorial advisory board. Original papers should be sub-

mitted for consideration to the editor, Dr. Fred W. Stewart, 444 East 68th Street, New York 21, New York. *Cancer* will be published bimonthly, at eight dollars a year, by Paul B. Hoeber Incorporated, Medical Book Department of Harper and Brothers.

## CORRESPONDENCE

### EFFECT OF ENVIRONMENTAL INFLUENCES

To the Editor: Just about twenty five years ago Professor Hermann J. Muller read a paper at the Second International Congress of Eugenics demonstrating that external influences do not increase the mutation rate in animals—in other words, that they have little to do with hereditary processes.

Last year the same distinguished scientist received the Nobel prize for proving that environmental influences especially radiations of various types enormously increase the mutation rate. This in itself is of human interest in that a man completely changed his opinion in twenty five years but what is more important is that Professor Muller has a real deal to say about the danger to the human race from radiations and radioactive substances of all kinds. Since most of the mutations are either lethal or defective, it seems that the damage need not appear at once. His article in the September number of the *Journal of Heredity* culminates in a very portentous warning to the medical profession that the use of radioactive substances may be associated with harm to the race of a kind not at all apparent at once. In fact the front cover of the journal is wholly given over to this warning.

Every man who undertakes the use of radioactive substances of any kind whether for therapy or investigation should read this great geneticist's paper which incidentally was read when he received the Nobel prize. He speaks not only of the dangers of x rays but also of mustard gas and of ultraviolet radiation. We are going ahead rather fast in the use of radiated atoms and molecules in the treatment of disease and also in the investigation of physical processes. It might be well to study the germ plasm—that is the substance of ovary and testicle—at the same time that studies are being carried out on the thyroid gland or whatever part of the body is being bombarded for therapeutic or investigative purposes.

Medicine is in a dangerous position. It has at hand powerful instruments which it often uses without due regard for the welfare of the patient as a whole. Similarly the use of mineral oil for constipation has been assumed to be an innocuous way of regulating one of the functions of the gastrointestinal tract. Now it appears likely that this is a way of preventing the absorption of vitamin A.

Boston

ABRAHAM MYERSON, M.D.

### DEPRIVATION OF LICENCE

To the Editor: At the meeting of the Board of Registration in Medicine held January 15 the registration of Dr. Daniel Kaplan of Worcester was suspended for three months because of gross misconduct in the practice of his profession.

## BOOK REVIEW

*Human Genetics*. By Reginald R. Gates. B.Sc., Ph.D., D.Sc., LL.D. 8° cloth two volumes 1318 pp. with 325 illustrations. New York: Macmillan Company, 1946. \$15.00.

This monumental treatise is essentially a reference work. It is based on the author's previous book *Heredity and Eugenics*, published in 1923, but the number of chapters has been doubled and the amount of material increased fivefold. The relation of heredity to all diseases and abnormalities is discussed in detail. The first chapters deal with the general principles of heredity in man, human cytology and linkage. These are followed by special chapters on the diseases and abnormalities of the various organs and systems and on general diseases and conditions. Of special interest are the chapters on color blindness, albinism, metabolic defects

hemophilia, blood groups, allergy, hereditary syndromes, sexual and intersexual conditions, twins and twinning, cancer, constitution, body build and susceptibility, stature and size and anthropologic characters. The text is well arranged and well written in an easy style. Selected references are appended to each chapter. A comprehensive index concludes the work. The book is well published in every way. It is a delight to read the handsome, clear type on good paper. The treatise is recommended for all medical, scientific, college and public libraries and should prove useful to all physicians.

### ANNOUNCEMENTS

Dr Louis S Chase announces the removal of his office to 416 Marlborough Street, Boston

Dr Clarke Staples announces the removal of his office to 543 Highland Avenue, Malden

Dr Donald M Stewart announces the opening of an office for the practice of obstetrics and gynecology at 745 Main Street, Fitchburg

### NEW ENGLAND HEART ASSOCIATION

The next meeting of the New England Heart Association will be held in the amphitheater of the Dowling Building, Boston City Hospital, on Monday, March 1, at 8 15 p m. Dr Laurence B Ellis will preside.

#### PROGRAM

Experience with Dicumarol in Acute Myocardial Infarction. Drs E Bresnick, L B Ellis, H N Hultgren, B Rapoport and H S Sise.

Venous-Pressure Responses to Exercise and Abdominal Compression. Dr H N Hultgren.

Observations on the Heart in Women. Dr B E Hamilton.

Circulatory Dynamics in Myxedema. Drs R A Bloomfield, L B Ellis, W K Long, G Maresh, J G Mebane and J P Milnor.

Evaluation of Vitamin E in the Treatment of Angina Pectoris. Drs I B Ravin and K H Katz.

Two to Three Year Follow-up on Penicillin-Treated Cases of Subacute Bacterial Endocarditis. Dr B Rapoport.

Interested physicians and medical students are cordially invited to attend.

### APPOINTMENT OF COMMISSIONED OFFICERS IN NAVY MEDICAL AND DENTAL CORPS

The statutory authority contained in Public Law 365 of 80th Congress, Title II (Army-Navy-Public Health Service Medical Officer Procurement Act of 1947), makes it possible for civilian doctors to become commissioned officers in the regular Navy, with ranks up to and including that of captain, provided they meet the professional and physical qualifications.

To qualify for appointment a doctor must be a citizen of the United States and a graduate of a Class "A" medical school and must have served at least one year's internship in an approved hospital. Candidates will then be judged on a number of qualifications, such as membership in a specialty board, teaching connections, the number of years of professional or scientific practice and hospital or laboratory connections.

Interested physicians should apply to the Bureau of Naval Personnel, Bureau of Medicine and Surgery, Navy Department, Washington, D C.

### MEDICAL AND SURGICAL POSITIONS IN OVERSEAS ARMY HOSPITALS

Opportunities for advanced training and experience in the various special fields of medicine and surgery in overseas Army hospitals are available. These hospitals are registered

with the American Medical Association, and the training may be acceptable by the specialty board as part of the period usually required to be spent in limited practice and experience prior to admission for examination. Interested members of the medical profession who have completed the formal training requirements for certification in one of the special fields are eligible to apply for these positions.

For information concerning the specialties and the location of hospitals, as well as the terms under which physicians may avail themselves of the training, application should be made to the Surgeon General, United States Army, Washington 25, D C.

### NATIONAL TUBERCULOSIS ASSOCIATION TEACHING AND RESEARCH FELLOWSHIPS

National Tuberculosis Association teaching and research fellowships in the field of tuberculosis are available; it was recently announced. Annual stipends for the fellowships will range from \$2400 to \$3200. Provision will also be made for laboratory fees and similar incidental expenses. The fellowships will be limited to graduates of American schools for teaching and investigation in the United States. Although preference will be given to applicants with a degree of Doctor of Philosophy or Doctor of Medicine, fellowships will not be restricted to the holders of these degrees. Applications will be considered in the fields of pathology and bacteriology, clinical medicine, epidemiology and social and statistical research. Applicants may elect the institutions in which they wish to study.

Persons interested in obtaining a fellowship should write to Dr James E Perkins, managing director, National Tuberculosis Association, 1790 Broadway, New York 19, New York, for further information.

### KENFIELD MEMORIAL FUND SCHOLARSHIP

A scholarship of \$100 will be available in 1948 for training of teachers of deaf adults. Applicants, in addition to being adult residents of the United States should meet the following requirements: personal characteristics necessary for successful teaching, ability to read lips as certified upon examination by an approved instructor in lip reading, a bachelor's degree, or two years of college work or successful experience in teaching in public or private schools, in addition to twelve semester hours of work in adult education, psychology of the handicapped, voice production and control, social service or kindred subjects, and thirty clock hours of private instruction under an approved teacher of lip reading or sixty clock hours of instruction in public-school classes under an approved teacher of lip reading. The winner of the scholarship may take the normal course from any normal training teacher or school or university in the United States offering a course acceptable to the Teachers' Committee of the American Hearing Society. The applicant for the scholarship must be a prospective teacher. Applications from those who are teaching lip reading now cannot be considered. The scholarship must be used within one year from the granting of the award.

Applications must be filed between March 1 and May 1, 1948, with Miss Rose V Feilbach, 2431 14th Street, N W, Washington 9, D C.

## INTERNAL PUBLIC RELATIONS\*

JAMES RAGLAN MILLER, M.D.†

HARTFORD, CONNECTICUT

IN CONNECTICUT it is a custom for the principal officers of the Medical Society to attend each of the eight county medical association meetings. These occur twice a year, and although riding circuit is an arduous task, it is worth while in the interest of good internal public relations, for the members of the Society are considered the first public. At these meetings the members have a chance to tell the state officers what they believe is wrong and what they suggest should be done about it, and the officers on their part have an opportunity to interest the members, if they can, in the projects of the Society. I am sure that every well organized state society attends to this need in some manner.

I am glad to see developing the habit of having someone from the American Medical Association as a speaker at every state medical society meeting. When Dr. Metcalf was unable to obtain the speaker he desired for this occasion, he turned to me and I told him that I was glad to do what I could. Though I cannot deliver a brilliant oration or provide entertainment with wit and humor, I can perhaps convince you that the Board of Trustees is a very human group. It endeavors to be close to the individual members, and in carrying out the directives and operating under the policies laid down by the House of Delegates, it must at all times bear in mind the effect of its actions on the medical profession in America.

This opportunity allows me to express my high appreciation of the activities of the New Hampshire delegate, Dr. Deering Smith. Anyone who follows the transactions of the House of Delegates of the American Medical Association will learn firsthand the careful attention that is given to his wise counsel.

The aim of any public-relations program should be to promote favorable consideration by the public of the organization and of the product that it offers. The title chosen for this occasion emphasizes the importance of having a sound product, of ample production, and of having a well informed sales

force. The cynic may question, "Why have a sales campaign?" And, indeed, it seems almost unnecessary to ask the public, which has had confidence in the profession for a hundred years or more, to think even more favorably of us. I do not propose to argue the needs of a positive campaign for public approval. It may be said, however, that there is a general opinion that the public holds the individual physician in high regard but is not so clear in its approval of the medical profession as an organization.

I believe that this criticism of organized medicine is losing its force. Most of the bitter criticism comes from those who wish to alter the basic structure of the whole American way of life. Suffice it to say that the House of Delegates has directed that positive steps be taken to place more effectively before the American people the accomplishments of the medical profession and its part in meeting the needs of the people for medical care. Anyone who went to the centennial celebration of the American Medical Association at Atlantic City must have had a feeling of pride as he saw demonstrated the important position that the medical profession occupies in the hearts and minds of the American people.

Today I shall consider some of the things that I believe we can do within our organization better than we have in the past so that our own members to the last man can be proud of the organization, and so that the profession itself may need less often to apologize or to give excuses for the action of any of its members. This is the area of internal public relations, which must be sound if we are to have healthy relations with the public at large.

The American Medical Association is a large federation of state organizations in which the county societies as the basic units occupy a conspicuous position of power and local responsibility. The complex problems and great responsibilities of large county associations whose membership runs into thousands will differ greatly from those handled with comparative ease by a small county association. The small society presents a special problem for its parent organization. For all practical purposes the

\*Presented at the annual meeting of the New Hampshire Medical Society, Newcastle, New Hampshire, June 20, 1947.

†Visiting obstetrician and gynecologist, Hartford Hospital.

state society must function on its behalf and with its co-operation. On the other hand, a large county society may be led by reason of its size and power to usurp some of the legitimate functions of the state organization and to exert undue influence within the state society to the detriment of the small county association. We have had enough of jurisdictional disputes elsewhere, and we do not want them in medicine.

Within the profession there are also many local societies — academies of medicine whose primary interests are in developing scientific programs. Occasionally, a local group of physicians organizes for purposes of dealing with economic problems of practice, especially for the provision of medical care to indigent groups. These are useful and sometimes indispensable means for dealing with local problems that may be too small to be handled by a large county or state association, but all these developments should be made harmoniously if the public is not to be confused.

Hospital staffs also have meetings and develop educational programs for their members and for the physicians of the community. Here is the proper forum for presentation of clinical papers and case reports, which formerly contributed so largely to the programs of local societies. Again, specialists and many general practitioners are drawn to meetings of national and regional societies. All these programs, as a rule, are in the nature of postgraduate education, and have little to do with the economic, legislative or other activities that concern physicians most in their relations with the public. Great care must be taken that the county associations, which are the functional units of the medical profession, are not so starved that they do not perform the necessary social tasks expected of the profession. Perhaps the answer to this question is in the development of a stronger and better functioning state organization.

There is no doubt that the New England town meeting is one of the finest examples of democratic government. When, however, the town becomes too large, the town meeting has to give way to another form of government. The successful politician must remember that extraordinary effort is required to make up for the loss that the citizen feels when he no longer has his customary forum for making known his wants — the larger the organization, the more difficult it is to make up for this loss. These developments must take place without making the individual physician feel that he is remote from those who direct his affairs.

In spite of many distractions it has amazed me to see how much devoted service is given to organized medicine and to the mechanics of providing better facilities for physicians by the very men who are busiest. I have observed that the vast majority of so-called "medical politicians" have risen to their positions primarily because they are respected by

their fellows as physicians. My first impression on beginning my duties as a delegate was one of admiration for a system that brought to the top so many physicians of high quality. The exceptions are conspicuous indeed.

During the war the staff at the American Medical Association headquarters was greatly depleted, and we are not yet fully caught up with our back work. That was part of the price we paid for the war, and it is a contribution of which every physician can be proud. It was inevitable that contacts between state societies and the American Medical Association during this period should have been deficient, and it was inevitable that criticism came from individual physicians who in their remote posts about the world had ample time to think upon the wrongs of the world in general and organized medicine in particular. Most physicians on sober reflection, however, will understand the situation. I am glad to report that the staff is now being filled with competent men who, under the direction of the Board of Trustees, are pursuing a program to develop the responsibilities of the profession to the public and also to develop more intimate and frequent contacts with the members who carry on the burden of state and county activities.

One of the means developed to bring the Association closer to the individual member was the so-called "Grass Roots Conference" at Atlantic City, where county officers had a meeting of their own and a chance to discuss the problems that concerned them.

The American Medical Association is also assisting in the development of regional conferences attended by the responsible officers of the state societies in that particular region together with members of their important committees. I believe it was Dr. Fishbein who once said that the burden of organized medicine is carried by about 3000 physicians in the United States. These are the men who make up these conferences. Not only are there discussions of problems that are of interest to the members but also officials of the American Medical Association are present to report to them and to learn from them, for this is a two-way affair. In New England we have gone still farther, as you know, by the organization of the Council of the New England State Medical Societies. This council meets three or four times a year, and since it consists of only three or four delegates from each state society, it is small enough to come to grips with the problems that are of peculiar interest to us in New England.

The productive life of a state society as an organization is most often found in its strong and active committees. These committees interest themselves in medical-care plans, legislation, care for the chronically sick, cancer, public health and hospitals — subjects that vitally affect relations with the public.

I recommend the institution of a program that we have found effective, and one that immeasurably increases the vitality and significance of these committees. At present in Connecticut there is scarcely a board or commission that has to do with health or welfare on the state level to which there has not been added a carefully chosen member of the Society. This is effective not only in keeping the Society informed and in representing the Society's interest but also in revealing ways and means whereby organized physicians may exert necessary leadership in a field that it is their obligation to develop. Members of these commissions lend weight to the deliberations of their committees.

The late George Vincent once said in explaining why Denmark had such an excellent health situation: "In Denmark every health officer is a physician and every physician is a health officer." I firmly believe that that is a desirable aim for the medical profession in the United States. We must develop a keener appreciation of our position of public trust. We must accept even more fully the obligation that goes with the trust. This is easily understood by the physician who works alone or with a few others in a small community where he has intimate contact with his chief selectmen and with the overseer of the poor, the chief of police and so forth, and perhaps he may occupy the post as local health officer. It is difficult, however, for the physician who lives in a large city to sense his public responsibility. At best he must express himself vicariously by means of the officials of his medical society, but it is his duty to see that his society fulfills its obligation in this regard, and if young men at the beginning of their professional lives do not see the example of their elders, they too will develop habits of indifference.

I recommend for consideration the advantages of developing a student membership in the state society. We have done this in Connecticut and have found it productive of good will among the young physicians. Unfortunately, medical students are likely to hear much of the alleged advantages of socialization of medicine by physicians who themselves have not indulged in personal medical practice. On the other hand there are few opportunities for them to hear what organized medicine is doing and can do for society.

I know that you have no medical school, but some of your New Hampshire boys are studying medicine elsewhere and are going to come back to be future members of this society, and you have interns and residents in your hospitals. I suggest that you concern yourselves with what they are thinking. Find out who they are and where they are studying and let them know that your society is interested in their welfare. Our student members, who now number 350, are very grateful for the copies of the *Connecticut State Medical Journal* that we send them.

The following arrangement has been found productive in Connecticut. About six years ago the

Connecticut Medical Examining Board, members of which are appointed by the Governor on nomination by the state society, foresaw the advantages of a close alliance between the Society and the Board, and as a result the executive secretary of the Society became the secretary of the Examining Board. This arrangement provided full-time administration for the Board as well as for the Society, and every prospective candidate for medical licensure came to the Society's office for his first contact. Dr. Barker, in his annual report to the Connecticut House of Delegates, made the following statement:

The good effect of this system cannot be measured. Most of the candidates come to the office for interviews and information and it is a surprising but none the less true observation that these physicians newly come to our state are more familiar with the activities and services of the Society's office than are many members of the House of Delegates. It is common for these candidates to ask even before they are settled here how they may become members of the Society either by transfer or election. All this is a privilege and an advantage that I believe no other state society enjoys and is the outcome of far sighted planning.

The advantages of this relation were even more apparent during the war when the executive secretary, Dr. Barker, was also the state chairman for the Procurement and Assignment Service. The result has been that the files in the office of the Society are not only complete but also official. We plan to have our physicians with us from the cradle to the grave.

Most of us, I believe, are out of sympathy with those who criticize national foreign policy before foreign audiences, and most physicians have little regard for would-be medical statesmen who attempt to bring pressure on organized medicine by arguing their ideas before lay audiences. With rare exceptions these dissident physicians have not participated as active members in the ordinary work of medical societies. They have rarely presented their arguments successfully before the organizations of medicine, and few of them have ever practiced individual medicine, which they so freely criticize. A reasonable opportunity should be given such persons to present their ideas before medical societies and to subject themselves to the discussion of the facts of life of medicine. I am sure that it would do them good.

What about the "lone-wolf" member who never comes to medical meetings? What about the occasional member who stays within the letter of the law, overcharges the poor and skates on the thin ice of professional respectability? I am sure that such members are few in number, but one bad apple has an effect on the whole barrel, and the adverse publicity caused by one unscrupulous physician brings the whole profession into disrepute. Some laymen believe that this is the most important item on the medical society's agenda. They point to the reluctance of physicians to bring to book a fellow member. This reluctance, they say, gives relative immunity to this sort of racketeer. The layman

points out that disciplinary action can be undertaken effectively only by the medical profession itself and that the legal profession has devised a powerful grievance committee to process complaints of unprofessional conduct against any lawyer. He will often add that the committee is not called on as often as he would like to have it, but it is there and no lawyer relishes a summons to appear before it, perhaps the grievance committee was devised because a lawyer on being admitted to the bar becomes an officer of the court, and since the court is sensitive to any unprofessional action, the bar association itself undertakes to discipline its own members.

Medical-insurance plans have extended their benefits widely as in New Hampshire and many other states. There develops a need for handling complaints that may originate with the medical-insurance administration, with the individual physician or with the individual patient. Every so often the "lone wolf" has to be trapped and has to be tamed. I am told that the grievance-committee mechanism works well when it is set up and used, and the very fact that it is there has a restraining influence.

When plans for prepaid medical service in Connecticut were being discussed, I pointed with pride to the experience in New Hampshire with the indemnity type of contract and, explained that, although there was no written agreement, the indemnity payments actually constituted a fee table for the indigent — that is, a gentleman's agreement that the table would be sufficient without further

charges when the family income is low. One of our cynical businessmen remarked that such an arrangement might work well in New Hampshire but not in Connecticut. I granted the New Hampshire part of the statement but was inclined to resent the implication that Connecticut waters were infested with sharks, until he told us of a man in his employ whom the physician charged inappropriately considering his reduced circumstances. I am a good organization man and I shall always defend another physician so long as I am convinced of his integrity and fair dealing, but I deeply resent actions that give physicians a bad name by causing hardship to a poor patient and I therefore recognize that proper policing of our own membership is one of our major responsibilities. This is a job that must be done with fairness and firmness, and with rare wisdom, and it is a job that falls naturally on the shoulders of the elders. I am glad to talk freely about self-discipline before a state society that needs it less than any I know, but I do not doubt that even you will have some experiences with shark fishing.

The ten-point health program of the American Medical Association is a fine statement of practical idealism. Parts of this program are already being put in motion by organized effort, but like the Ten Commandments many elements of the program depend upon personal integrity in the daily life of every physician. Effective public relations come from within. Our own members are our first public.

## POSTARSENICAL ENCEPHALOPATHY IN THE TREATMENT OF SYPHILIS IN WOMEN\*

S CHARLES KASDON, M D,† AND MORRIS W SHAPIRO, M D ‡

BOSTON

AT LEAST 60 per cent of adults receiving arsenical antisyphilitic therapy who develop postarsenical encephalopathy are pregnant women. The mortality in this most serious complication in the treatment of syphilis approaches 70 per cent. Postarsenical encephalopathy, the term considered most apt, has also been described under the following titles: cerebral purpura, serous apoplexy, hemorrhagic encephalitis, pericapillary encephalorrhagia, medullary perivascular necrosis and toxic encephalitis.

There is a widespread lack of familiarity with this cause of death in 13 per cent of the total number of patients treated by the massive five-day arsenical

course.<sup>1</sup> Postarsenical encephalopathy was the cause of 95 per cent of 211 maternal deaths in Arnell and Guerriero's<sup>2</sup> series, 27 per cent of maternal deaths in Kennedy and Hennington's<sup>3</sup> group and 8 deaths in five years at the University of Iowa clinics.<sup>4</sup>

This paper reports 2 fatal cases of postarsenical encephalopathy, 1 in pregnancy, with autopsy findings in both, and also presents several new factors in its management. These new developments are important in spite of the recent advent of penicillin therapy for syphilis, since there is little question that many patients receiving antisyphilitic therapy will be dependent upon arsenicals for some time to come.

### SYMPTOMS

The clinical picture that is characteristic of this syndrome is most conveniently described by a noso-

\*From the Department of Obstetrics and Gynecology and the Department of Pathology, Carney Hospital and the Department of Pathology, Tufts College Medical School.

†Junior assistant surgeon, Department of Gynecology, Boston Dispensary, consultant in gynecology, Joseph H. Pratt Diagnostic Hospital.

‡Instructor in pathology and bacteriology, Tufts College Medical School, pathologist, Carney Hospital.

graph suggested by Kühnel.<sup>4</sup> The patient is a young woman, usually pregnant, and generally with a past history of good health except for the presence of syphilitic infection. The disease is often of fairly recent origin or, in any case, manifest by recent signs of active infection. It may, however, be a latent infection, generally untreated previously and with very little evidence of syphilis except for the positive serologic findings. Antisyphilitic treatment is begun in the last trimester of pregnancy with arsphenamine or one of its related drugs, with two to four injections of average dose, and the patient may lack symptoms for two to five days. Many patients have transitory but intensely significant complaints, such as slight headaches, nausea or vomiting, or both general indisposition, restlessness and, rarely, a rapidly fading exanthem, after which there is a rather sudden onset of headache, dizziness, malaise, nausea and vomiting with a moderate leukocytosis. Within twenty-four hours marked restlessness ensues, with mental confusion followed by an irregular number of convulsions and coma. At this stage the patient is taken to the hospital with a diagnosis of eclampsia. Later — from a few hours to one day — irritative cerebral symptoms become more pronounced, including trismus, tetany, accentuated reflexes, a positive Babinski sign and the irregular respiratory phase of Cheyne-Stokes type. Death follows deepening coma. In most cases death occurs three to five days after the acute onset.

#### INCIDENCE

It was scarcely two years after the introduction of arsphenamine in the treatment of syphilis by Ehrlich when hemorrhagic encephalitis as a toxic manifestation of this therapy was reported.<sup>6-8</sup> The literature since that time has had many reports dealing with the most frequent cause of death in the treatment of syphilis.<sup>10</sup> Glaser, Imerman and Imerman<sup>11</sup> (1935) reviewed the literature and culled 155 cases, adding 3 of their own. Smith and Newbill<sup>12</sup> found 17 more to report by 1939. Since that time a review of the literature available from 1939 to 1946 has offered 88 new cases.<sup>13-16</sup>

The incidence of arsenical encephalopathy in patients treated for syphilis by the multiple-course method is variously quoted as 1,2500 cases,<sup>17</sup> 1:6500<sup>11, 14</sup> and 1:2000.<sup>18</sup> That arsenical encephalopathy occurred with greatest frequency in pregnancy has only recently been appreciated. In 36 reported cases of encephalopathy in adult women studied in the literature from 1939 to 1946, 27 (75 per cent) were pregnant. This shows close agreement with the incidence during pregnancy of post-arsenical encephalopathy in the reports of Ingraham<sup>19</sup> (64.3 per cent), Meirovsky and Kretzmer<sup>11</sup> (60 per cent), Cormia<sup>12</sup> (80 per cent) and Paley and Plehette<sup>10</sup> (70 per cent). Arnell and Guerriero<sup>2</sup> reported that fatal arsenical encephalopathy is four

times more frequent in pregnant than in nonpregnant women.<sup>20-21</sup>

In spite of the wealth of evidence that the treatment of syphilis in pregnant women should be undertaken with grave circumspection and only when clearly indicated, conflicting views still exist in the attitude of syphilologists and even more so in the minds of obstetricians, upon whom the responsibility for treatment rests primarily. For it is the obstetrician who almost universally discovers the presence of syphilis in pregnant women and must decide whether treatment is warranted or not. Some writers convey the impression that pregnant women with syphilis tolerate arsenical therapy well.<sup>22-24</sup> However the general consensus contradicts this attitude. The most acceptable impression, as stated by Plass and Woods,<sup>4</sup> is that "a pregnant woman is probably more susceptible to the deleterious as well as the beneficial effects of modern arsenical therapy."

#### PATHOGENESIS AND ETIOLOGY

That typical lesions are not entirely dependent upon arsenicals has been demonstrated by reports of cases in which no arsenic has been administered.<sup>25-28</sup> The overwhelming number, nevertheless, follow the use of pentavalent arsenic.<sup>29</sup> An unusually high frequency has been noted after the administration of sulfarsphenamine,<sup>31-33</sup> resulting in almost complete condemnation of its use.

Mapharsen is now employed almost universally in the massive five-day course<sup>34</sup> and other accelerated arsenical courses in the treatment of syphilis, but the incidence of severe central-nervous-system reactions remains at 1 per cent or more and the mortality from complications of therapy at 0.3 per cent.<sup>31</sup> It is obvious that when this relatively high incidence of severe toxic reactions in the accelerated arsenical therapy of syphilis is considered together with the increased susceptibility of patients with ante-partum syphilis, the cautious therapist should hesitate to subject his pregnant patients to the dangers of encephalopathy.

A clear statement of the mode of action whereby arsphenamine therapy results in encephalopathy was presented by Ehrlich<sup>35</sup> in 1914. He concluded that the mechanism was first a dilatation of the cerebral vessels followed by edema and perivascular hemorrhage. More recent studies<sup>36-38</sup> cling to this basic theory of development. Deficiency of vitamin C<sup>39</sup> and P<sup>40</sup> may play a part, but the production of typical lesions in the brain of normal rabbits with an adequate vitamin intake<sup>41-43</sup> throws doubt on these factors. The theory of the relation between nitritoid crises and vascular damage leading to cerebral edema is open to the objection that nitritoid crises have yet to be demonstrated in Mapharsen therapy.<sup>37</sup> Selzberger<sup>44</sup> and later Moriyama,<sup>45</sup> using patients' serum, were able to transfer arsenic sensitivity to guinea pigs. Landsteiner and Jacobs<sup>46</sup> demonstrated arsenic anaphylaxis in guinea

pigs. However, Gjessing<sup>70</sup> questioned whether arsenic sensitivity was the cause of the encephalopathy, since he reported a patient who recovered from typical clinical postarsenical encephalopathy and who received treatment with neoarsphenamine six weeks later with no untoward results. Klaften<sup>44</sup> corroborated this finding. In addition, a large number of cases have followed only one known arsenical injection. Tzanck and Lewis<sup>43</sup> rule out the Herxheimer augmentation of the virulence of the spirochete through treatment employed to combat it, since hemorrhagic encephalopathy has been too widely reported in nonsyphilitic patients. Osterberg and Kernohan<sup>71</sup> found arsenic in relatively large amounts in the brain analysis in doubtful diagnostic problems, as did Gierlich and Kunkle.<sup>72</sup>

The explanations offered for the especially increased incidence of postarsenical encephalopathy in pregnancy are likewise many.<sup>73</sup> Arnell and Guerriero<sup>2</sup> believed that the increased incidence in pregnancy was explained by the greater storage of arsenic in the placenta that had been demonstrated by Eastman and Dippel.<sup>74</sup> This was gradually set free in the blood over a period of several days, thus increasing the circulating amount of arsenic. Pregnancy presumably produces a degree of capillary alteration that is further aggravated by the action of arsenic on the capillaries, resulting in the toxic phenomena.<sup>46, 75</sup> Excessive protein deficiency in pregnancy suggested as a predisposing cause is not conclusive, since many have noted that a large number of women with ante-partum syphilis and many with marked debility and toxemia have been treated with arsenic without a noticeable increase in the development of encephalopathy in this group.

#### TREATMENT

The management of acute postarsenical encephalopathy in pregnancy can best be approached from the prophylactic or preventive standpoint, secondly, the major principles of treatment and thirdly, the specific agents that are of value in the management of the acute toxic state.

Preliminary treatment with bismuth or mercury compounds has no effect whatsoever in preventing encephalopathy during gestation. The dosage level of the arsenical used is also of undetermined importance,<sup>12</sup> since many cases follow very small quantities of arsenic. The undeniable increase in frequency of this complication during the massive five-day course of arsenical treatment in syphilis tends to direct more interest toward the amount of arsenical administered. It is therefore believed that minimal dosage levels are to be preferred. The essential fact that positive and unequivocal evidence of syphilis in pregnancy must be obtained before arsenical therapy is undertaken deserves great stress. In the light of modern opinion, ante-partum treatment with arsenic for syphilis is not necessary when adequate therapy has already been administered.

The concept that patients in the last trimester of pregnancy are more susceptible to encephalopathy is probably due to the fact that in the past the greatest number of patients were not seen by the physician until late in pregnancy. Actually, encephalopathy has been described in all but the first month of gestation. In the series of 50 cases collected from the literature of the past ten years the average duration of pregnancy was five and four-fifths months. It is certainly likely that the date of onset of treatment is more important than the "metabolic overload" that occurs at the end of pregnancy. It is also certain that the arsenical treatment of pregnant women who have a history of sensitivity to arsenic or other metals is at best hazardous. Penicillin is unquestionably the drug of choice, since encephalopathic changes have yet to be reported in the treatment of syphilis with penicillin.

The major principle of treatment for this toxic reaction is also clear. There is little question that therapy is more effective if instituted before the onset of coma and convulsions. It is possible to start treatment before the severe symptoms develop, since the prodromal signs of slight headache, nausea or vomiting, or both, generalized indisposition, restlessness and the relatively infrequent exanthem usually precede the onset of convulsions and coma by one or two days. If the physician is aware of these significant but mild signs of warning following the administration of arsenicals the prompt institution of adequate treatment before coma and convulsions ensue is at present the only means of reducing the mortality from this complication in the treatment of syphilis with arsenicals.

The intramuscular administration of adrenalin hydrochloride in a 1:1000 solution in repeated dosage has long been in favor. The rationale for its use has been presented above, but in spite of the proclaimed specificity of adrenalin-like substances, the mortality has remained high. Much stress has been placed on the thiosulfates in the treatment of arsenical toxicity, but it is generally admitted that their action has a very slight and definitely questionable value. The long list of additional drugs and vitamins that have been used, such as sodium dehydrocholate, calcium chloride, numerous sedatives, magnesium sulfate, components of the vitamin B complex, acetylcholine, vitamin K, vitamin C and vitamin P, has not appreciably altered the course of the disease. Perhaps as great stress has been placed on reducing the tendency to cerebral edema by means of hypertonic solutions and especially by spinal-fluid drainage. In fact, Ransome et al.<sup>1</sup> kept all their patients in the erect sitting position throughout the whole course of treatment and reported no mortality in the 5 cases studied. Their explanation for the effectiveness of this technic is fallacious since the reduction of cerebrospinal-fluid pressure and cephalic venous pressure, which they claim as the cause of improvement, can at best

have been very transitory. In view of their reported results, however, additional evidence for the efficacy of the postural treatment is awaited.

Much more important is the newly introduced drug BAL (2,3-dimercaptopropanol),<sup>76-78</sup> a specific detoxifying agent for arsenic, mercury, gold and other heavy metals when injected intramuscularly or intravenously. The antidotal action of BAL is due to its ability to remove arsenicals from combination with the tissue-cell proteins with the excretion of a stable and relatively nontoxic substance. The dosage of BAL (10 per cent solution in peanut oil with 20 per cent benzyl benzoate) is 2.5 to 5 mg per kilogram of body weight, injected four times daily at four-hour intervals the first two days and then twice daily thereafter for six or more days. The maximum tolerated divided dose in rabbits is 100 mg per kilogram of body weight. The major reactions to BAL are "constriction in the throat," preternal oppression, burning of the lips, lacrimation, dryness of the mouth, local tenderness at the site of injection, nervousness, restlessness, nausea and vomiting. No severe toxic reactions have thus far been reported.<sup>79</sup> Eagle and Magnuson<sup>78</sup> presented 55 cases of postarsenical encephalopathy out of 227 toxic reactions to antisyphilitic therapy that were treated adequately with BAL. Of these, 24 patients developed coma or convulsions, or both, with a mortality of 25 per cent, when treated within six hours of the onset of symptoms. Those treated later than six hours after the onset of symptoms had a mortality of 45 per cent. In 15 mild cases, there was 100 per cent survival. The authors report an over-all reduction of mortality from 70 per cent to 11 per cent by the use of BAL. It promises to be of the greatest value in the management of the most severe toxic reactions to arsenic. A high-protein, high-carbohydrate and low-fat diet is advisable as well.

### CASE REPORTS

Two young women with asymptomatic syphilis came to post-mortem examination after neosarphenamine treatment. These therapeutic deaths occurred within a six-month period. One of these women was pregnant.

**CASE 1\*** V W (C. H. A-42-44) a 34-year-old woman became pregnant for the first time after treatment for infertility. She was 2½ months pregnant when first seen. The past history and family histories were completely irrelevant and examination at that time revealed no abnormalities of moment. A routine specimen submitted for examination showed a positive blood Hinton test. This was repeated, as well as a Wasserman test and all reports were returned strongly positive. Blood examination, physical examination and a careful review of the husband's history failed to reveal any evidence of syphilis to him. Routine premarital blood examination 2 years earlier had been reported negative. The patient was referred to a competent syphilologist for further diagnosis and suggestions for management. She received 0.2 gm of bismuth at weekly intervals for 6 weeks without reaction and then was started on neosarphenamine. The first dose of 0.3 gm was given 10 days and the second

dose 3 days before admission. On the day she received the second dose of neosarphenamine she also made a routine visit to her obstetrician who found a blood pressure of 100/70; the urine contained no albumin, and there were no toxic signs or symptoms. For the next 2 days the patient had headaches, epigastric distress, unusual restlessness, massive gaseous eructations, chilly sensations and no bowel movements. On the 3rd morning she was found lying in bed in a semicomatose state with frequent bouts of stertorous breathing, repeated extensor tonic convulsions at intervals of 5 to 8 minutes, excessive salivation and moderate generalized cramps. The convulsions lasted about 40 to 60 seconds; the patient remaining semicomatose between seizures. The physician who was called in to see her believed that she was suffering

FIGURE 1 Coronal Section through Cerebral Hemispheres (Case 1)

Note symmetrical distribution of petechial hemorrhages, confluent in areas and confined for the most part to the white matter. The corpus callosum and the internal capsule show marked involvement.

from eclampsia, and the patient was admitted to the hospital on October 19, 1942.

Physical examination revealed an acutely and seriously ill woman, who was having convulsions lasting 1 or 2 minutes and occurring every 5 to 8 minutes with extensor spasm of both arms and legs, a moderate degree of opisthotonus, stertorous breathing, excessive salivation and moderately severe cyanosis. She did not respond to commands. The deep reflexes were hyperactive and the Babinski reflexes extensor in nature.

The temperature was 98.6 F, the pulse 96 and the respirations 36; the blood pressure was 84/50.

Examination of the blood disclosed a red-cell count of 3,520,000 with a hemoglobin of 78 per cent, and a white-cell count of 20,800 with 90 per cent neutrophils, 6 per cent lymphocytes, 2 per cent monocytes and 2 per cent band forms. The blood Hinton reaction was ++++. The nonprotein nitrogen was 22.4 mg per 100 cc. Blood culture showed no growth. Urinalysis was negative.

The convulsions were controlled with 0.016 gm of morphine sulfate and 0.2 gm sodium luminal intravenously. A total of 500 cc. of 10 per cent glucose in water was given intravenously.

A lumbar puncture was performed and the spinal fluid findings were as follows: 101 white cells and 107 red cells per cubic millimeter, a total protein of 300 mg, and a sugar of 51 mg per 100 cc. and a chloride of 900 milliequivalents per liter. A direct smear revealed 60 per cent polymorphonuclear leukocytes and 40 per cent lymphocytes, no organisms were seen. The spinal fluid Wasserman reaction was negative.

The diagnosis was toxic encephalopathy of undetermined nature following arsenical therapy. In spite of the control of convulsions by adequate sedation the patient's course was rapidly downhill and she expired 22 hours after admission.

\*Reprinted through the courtesy of Dr. L. E. Phaneuf.

At post-mortem examination, which was performed 2½ hours after death, the outstanding gross findings were seen in the brain, which was heavy and weighed 1525 gm. There was no epidural or subdural hemorrhage. The pia-arachnoid was transparent, and its vessels were congested. It was hemorrhagic over the pons and the medulla. Multiple sections revealed innumerable capillary hemorrhages, confluent in areas, symmetrically distributed throughout the white

CASE 2\* H G, a 31-year-old woman was known to have had syphilis for the past 10 years. She had one child 9 years old, who was living and well. Because of a persistently posi-

FIGURE 2 Section through Pons (Case 1)  
No confluent areas of hemorrhage, with softening

matter of the brain. Softening and necrosis was most marked in the pons, medulla, cerebral peduncles, the corpus callosum, and the internal and external capsules (Fig 1 and 2). The vessels throughout were congested, and the cut surface was moist. The ventricular system was intact and regular and contained cloudy cerebrospinal fluid. The cervical cord was free of disease.

The remainder of the organs of the body showed severe congestive changes, the typical findings of pregnancy and ter-

минаl cardiac failure. There was severe passive congestion and central necrosis in the liver.

Microscopically, the brain showed two basic lesions: punctate and ring hemorrhages, with injury of the capillary walls, and often secondary mural and obstructing thrombosis. In areas there was beginning secondary infarction of the brain tissue.

The second case, although not that of a pregnant woman, is included because of its similarity to the first in other respects.

days after the last dose of neoarsphenamine), she suffered the sudden onset of severe headaches followed in 6 hours by tonic convulsions and loss of consciousness. She was admitted to the hospital on April 15. At that time the extremities were spastic and the reflexes hyperactive, and she was in a comatose state. The temperature was 98°F, the pulse 88, and the respirations 16. The blood pressure was 140/70. The white-cell count was 13,500, and the red-cell count was 4,150,000. The urine was negative for albumin and sugar. The blood nonprotein nitrogen was 25 mg per 100 cc. A

\*Cambridge City Hospital Case A-43 20

lumbar puncture revealed clear spinal fluid under increased pressure. There were no cells present. The total protein was 56 mg per 100 cc. The gold-sol curve was 0000000000.

The patient died on the following day.

A post mortem examination limited to the head was performed 2 hours and 20 minutes after death. The brain weighed 1250 gm. The white matter of the corpus callosum the subcortical white matter of the hemispheres and the white matter of both internal capsules were riddled with innumerable fresh capillary hemorrhages. There were capillary hemorrhages into the ependyma of the lateral ventricles, with slightly blood tinged fluid in the lateral ventricles. These hemorrhages were symmetrically distributed. The cerebral peduncles, the pons the medulla and the cervical cord were free of disease. Microscopically the brain showed two basic lesions punctionate and ring hemorrhages with injury of the capillary walls, and often secondary mural and obstructing thrombosis (Fig 3) and thrombosis of the capillaries without hemorrhage, but with beginning secondary infarction of brain tissue.

It appeared that as a result of changes in the vessel wall hemorrhages or thrombosis or both resulted. The dura showed vascular changes, with bleeding similar to those in the brain.

### Discussion

Postarsenical encephalopathy due to neoarsphenamine is a well recognized clinical and pathologic entity. The disease is infrequent, occurring in about 1-6500 cases treated, and generally runs a rapidly fatal course, although recoveries have been reported in the literature. The average time of onset of symptoms after the last injection of neoarsphenamine is about two and a half days. In the cases reported above it was three days in Case 1 and fifteen days in Case 2. The usual number of injections previous to the onset of symptoms is two or three. In Case 1 it was two, and in Case 2 it was twenty-three injections.

Case 1 was in all respects typical of cases observed during pregnancy. The disease usually occurs during the last trimester of pregnancy in patients showing asymptomatic syphilis discovered on serologic examination. The onset early in the first course of injections of neoarsphenamine is common.

The convulsions occurring in the last trimester of pregnancy naturally bring forth a diagnosis of eclampsia on the part of the physician. However, the following differential points are present: a positive history of arsenical treatment, usually within three days, no hypertension, no albuminuria, no edema, and no toxic symptoms. The course is rapidly downhill, death occurring in two or three days in 70 per cent of cases until the advent of BAL as a specific detoxifying agent for arsenic.

The lesions in the brain in Case 1 were very extensive and involved the vital medulla. The liver cells also showed destructive changes, a rather unusual finding in postarsenical encephalopathy.

Case 2 was less typical so far as the number of injections and the time elapsing from last injection to onset of symptoms are concerned. The course of the disease and the autopsy findings were quite typical. The pathologic changes in the brain consisted of swelling of the endothelial cells of the capillaries,

congestion of vessels and edema of the brain, punctate and ring hemorrhages symmetrically distributed, thrombosis of the capillaries (fibrin thrombi), and infarction of brain tissue.

The pathogenesis of this disease is not entirely clear. Many theories have been offered to explain it. It appears, however, that the arsenicals are responsible in setting off a series of events that frequently culminate in the death of the patient. The first is definite damage to the walls of the capillaries, which is followed by hemorrhage of the ball-and-ring type and by thrombosis. Subsequently, the brain areas involved undergo infarction, with necrosis of brain tissue. The damage to the vessel walls is thought to be on the basis of allergy or sensitivity, in some manner greatly accentuated during pregnancy.

For the treatment to be effective, this condition must be recognized in the first few hours after the onset, and treatment promptly started. Therapy should include sedation and, most important of all, adequate and early administration of BAL, adequate treatment succeeds in lowering the over-all mortality rate from 70 to 11 per cent. The single most essential fact in control of this serious complication of syphilitic treatment with arsenicals is the application of therapy before the onset of coma and convulsions. It is possible to start treatment sufficiently early if one is aware of the prodromal symptoms that precede the onset of coma and convulsions. The most significant symptoms are headache, epigastric distress, restlessness and nausea or vomiting, or both. The use of penicillin as the drug of choice in the treatment of syphilis during pregnancy may prove to eliminate encephalopathy entirely and is therefore recommended. The use of intravenous arsenicals during pregnancy for any disease but syphilis should be condemned. Similarly, the diagnosis of syphilis should be unequivocally established and treatment clearly indicated before arsenical therapy is undertaken. The specific detoxifying agent for arsenic, BAL, deserves a wide use in the control of this complication.

### SUMMARY

The cases of 2 young women with asymptomatic syphilis who came to postmortem study after neoarsphenamine treatment are presented. These deaths due to therapy occurred within a six-month period. One of these women was pregnant and near term.

## MENINGOCOCCAL PNEUMONIA\*

## Report of Two Cases with Meningococcal Effusion in One

IRVING B. BRICK, M.D.†

WASHINGTON, D. C.

WITHIN a period of a month in 1942, 2 cases of pneumonia in which the meningococcus was implicated, without meningeal involvement, were observed. It has been known for some time that extrameningeal meningococcal infections are not uncommon,<sup>1</sup> but the attention directed to the respiratory phase of such infections is very scant. In view of the uniqueness of one of the cases observed and because of the lack of recent literature on the subject, it seemed worth while to report the cases and briefly to review the literature. The fact that most of the cases previously reported involved military personnel in World War I also affords an opportunity to review similar experience in World War II.

## CASE REPORTS

P. C. (B.C.H. 1088509), a 56-year-old man entered the hospital on November 24, 1942, because of chills and fever, cough and vague chest pain of 4 days duration. Physical examination revealed moist rales in the right axilla and a roentgenogram on the day of admission was reported as showing pneumonia of the right middle lobe. A blood culture taken before exhibition of sulfadiazine revealed a growth of Type 1 meningococcus. Neufeld typing of the sputum was reported as negative.

On sulfadiazine therapy from November 24 to 30 the patient made an uneventful recovery. A repeat x-ray film on December 3 was reported as being within normal limits. The white-cell count dropped from 14,100 on entry to 9150. Blood cultures on November 29 and December 7 revealed no growth and the patient was discharged on December 10.

In this case of pneumonia routine blood cultures showed a growth of Type 1 meningococcus. Since Neufeld typing of the sputum was negative for both the pneumococcus and the meningococcus the evidence that the pneumonia was meningococcal in origin is indirect but warrants attention. The response to sulfadiazine was characteristic of that expected in either pneumococcal or meningococcal infections and did not resemble the response of pneumonias of virus etiology.

L. L. (B.C.H. Case 1090910)† a 53-year-old baker's helper was admitted to the hospital on December 21, 1942 with complaints of pain in the left side of the chest of 3 days duration, hemoptysis of 3 days duration and rash on the legs of 1 day's duration. For the past 2 weeks the patient had had a "heavy" cough and had expectorated slight amounts of mucoid sputum, which was occasionally blood streaked. "Nearly" not feeling too well, he had been able to work "nearly" every day. However 3 days prior to admission he noticed a sharp pain in the left midaxillary region accentuated on deep breathing and coughing. Expectoration of

thick rusty sputum was noted on the same day. The symptoms became increasingly severe. On the day before admission a chill and fever were noted, and for the first time a red rash was seen on both lower extremities. The skin lesions were not painful, itchy or raised above the skin surface. The patient denied any previous similar manifestations.

The patient was unmarried and had been on relief for many years. He was a known chronic alcoholic of many years' standing. At the age of 20 he had had a penile sore and had been told that he had "had blood" many years before the present episode.

In January 1938 he had been seen in the Outpatient Department for shortness of breath. A positive blood Hinton test was noted. Physical examination showed an aortic diastolic murmur and the diagnoses of late latent syphilis, syphilitic heart disease with aortic regurgitation and generalized arteriosclerosis were entered in the record. A foot roentgenogram of the chest revealed widening of the ascending and descending aorta, raising the question of aortic aneurysm. After a few intramuscular injections of bismuth oil had been given the patient absented himself from the clinic.

Physical examination disclosed a markedly dyspneic poorly nourished man who grunted with every respiration. The face was flushed and dilatation of the aortic aorta was noted. Over the thighs, feet and legs there was a petechial rash the lesions being pin-point to 3 mm. in diameter, some were discrete and others confluent and did not blanch on pressure. The teeth were in very poor condition but the gums were firm and no bleeding was noted. The neck was supple and hernial and Brudzinski's signs were absent. Examination of the chest revealed limitation of respiratory excursions of the left hemithorax. Decreased tactile fremitus, marked diminution of breath and voice sounds and dullness on percussion were noted over the lower half of the left portion of the chest, extending up to the level of the third rib anteriorly and the fifth thoracic vertebra posteriorly. The trachea was deviated to the right. The apical impulse was not made out on palpation; there was sinus rhythm with a rate of 100 per minute, and an aortic diastolic murmur was heard best in the third left interspace. Neurologic examination was not remarkable. The patient was somewhat incoherent and confused but cooperative and euphoric.

The temperature was 101.8°F the pulse 118 and the respirations 34. The blood pressure was 130/100.

Examination of the blood demonstrated 11.0 gm. of hemoglobin and a white-cell count of 8950 with 84 per cent neutrophils and 17 per cent lymphocytes. The hematocrit was 36 per cent and the corrected erythrocyte sedimentation rate 35 mm. in 1 hour.

The sputum was thick, rusty and tenacious. Gram's stain revealed the sputum to be loaded with gram negative diplococci; the polymorphonuclear cells burst with these gram negative diplococci which had the morphology of meningococci. A number of gram positive diplococci outside the polymorphonuclear cells were also noted. Neufeld typing and culture revealed predominantly Type 1 meningococci with some Type 15 pneumococci.

A roentgenogram confirmed the impression that fluid was present in the left side of the chest. Thoracentesis was productive of 1250 cc. of serosanguineous fluid which contained 4500 leukocytes per cubic millimeter, 95 per cent of which were polymorphonuclear cells. Culture of this chest fluid on blood agar plates was positive for gram negative diplococci which were typed as Type 1 meningococci.

Blood cultures on admission before institution of chemotherapy and on the 3rd and 13th hospital days were negative for the meningococcus. Urinalyses were not remarkable and there was a positive blood Hinton test but negative spinal fluid Hinton and Wassermann tests. The spinal fluid examinations including culture were not remarkable.

\*From the Fifth and Sixth Medical Services (Boston University) Boston City Hospital.

†Instructor in medicine, Department of Medicine, Georgetown University School of Medicine; formerly resident, Fifth and Sixth Medical Services, Boston City Hospital.

†The bacteriologic studies in this case were made in the laboratory of Dr. Maxwell Finland, at the Thorndike Memorial Laboratory, Boston City Hospital.

ture The operation results in incomplete removal of the gland and recurrent obstruction

Believing that these operative procedures were far from satisfactory, Millin studied, on cadavers, a new approach to the prostate. He was convinced that since the prostate is essentially an extravescical organ, it should be removed by an extravescical approach. As a result of his studies the retropubic operation was devised.

*Preoperative preparation* The usual studies of renal and cardiovascular function are made before operation. Intravenous pyelograms are obtained. The patient is not catheterized unless there is urinary infection that fails to respond to treatment or unless renal function is poor. Urethral-catheter drainage is avoided if possible.

*Anesthesia* Low spinal anesthesia or Pentothal Sodium and nitrous oxide and oxygen are used. The patient is cystoscoped for the first time on the operating table.

*Operative technic* The bladder is exposed by a mid-line suprapubic incision. The prevesical space is opened and cleared of fat. A specially devised self-retaining retractor separates the rectus muscles and presses the bladder upward. The veins on the anterior and lateral aspects of the prostate are exposed and carefully studied, since their distribution varies considerably. These veins are situated in the prevesical layer of the pelvic fascia. A large central vein arises from the deep dorsal vein of the penis, other veins lie on each side. These veins are tied with the aid of a boomerang needle. The prostatic capsule is opened transversely, and bleeding points are grasped between toothed forceps. The incision is then carried down to the adenoma. The apex of the prostatic mass is freed from the capsule, and the dissection is continued up to the bladder neck. Here the prostate is freed by sharp dissection. Bleeding points are controlled by ligature or electrocoagulation. After removal of the hypertrophied gland a No. 18 catheter is passed through the urethra to the bladder. The prostatic capsule is closed with interrupted sutures. The abdominal wound is closed, a small drain being left in the prevesical space.

In his first 20 cases Millin reported no mortality and few postoperative complications. Since this first report Millin has performed over 400 retropubic prostatectomies, which he described at the July, 1947, meeting of the American Urological Association in Buffalo, New York. The mortality was approximately 4 per cent. Millin's enthusiasm for the procedure was unbounded. In his book describing the operation, he states that the extravescical retropubic approach to the prostate enables one to deal with all pathologic conditions within that organ and its contained urethra.<sup>3</sup>

Among the audience who listened to Millin's presentation, there were a few skeptics, consisting of some who had seen Millin operate and who had

performed retropubic prostatectomies themselves. Their enthusiasm seemed to be less than Millin's, tempered no doubt by their own experiences. The prevailing opinion, however, was one of considerable interest and an eagerness to go home and "try it out."

Since then little has appeared in our own literature concerning this new method of removing the prostate, although the few reports available have been favorable.

The recent French literature includes a description of retropubic prostatectomy with the report of 70 operations.<sup>4</sup> The mortality was low, 2 deaths, functional results were excellent, and the authors were enthusiastic about the operation.

There are reasons to believe that retropubic prostatectomy will have a very thorough trial in this country. I do not agree that Millin's criticisms of present methods of relieving prostatic obstruction are entirely justified, but I admit that there is some truth in his comments on these procedures. Although the perfect method of removing the prostate may not have been devised, I am not prepared to hand the laurel to retropubic prostatectomy until the long-term results are clear. The urologist should be able to perform all the well recognized operations for the relief of prostatic obstruction.

### *Carcinoma of the Bladder*

The classification of epithelial tumors of the bladder has always been confusing, and no one classification of these neoplasms has been generally accepted. The Tumor Registry of the American Urological Association, after a study of over 1200 sections of these tumors in 1936, decided that it was not practical to segregate bladder neoplasms into definite groups corresponding to their cell types. Jewett and Blackman,<sup>5</sup> after a histologic study of 97 cases of bladder tumor in which autopsy was performed, concluded that accurate classification of large infiltrating carcinomas of the bladder on the basis of cellular differentiation alone was impossible. Many classifications of these tumors in the past have been confusing because they were too complicated.

The present tendency is toward a simpler classification. In 1939 Ash<sup>6</sup> stated that morphologically the tumors fall into two groups, papillary and sessile. For the past seven years epithelial tumors of the bladder at the Massachusetts General Hospital have been classified as papillary and nonpapillary. Tumors in each of these groups are graded I, II or III according to their microscopical appearance.<sup>7</sup> Either the papillary tumors or the nonpapillary (sessile) tumors may infiltrate. This simple classification is essentially the same as that used by the Bladder Tumor Registry, as outlined by Dart<sup>8</sup> and Ash.<sup>9</sup> It has the advantage of correlating the gross or cystoscopic appearance of these tumors with their histologic characteristics. Most bladder

## MENINGOCOCCAL PNEUMONIA\*

## Report of Two Cases with Meningococcal Effusion in One

IRVING B. BRICK, M.D.†

WASHINGTON, D. C.

WITHIN a period of a month in 1942, 2 cases of pneumonia in which the meningococcus was implicated, without meningeal involvement, were observed. It has been known for some time that extrameningeal meningococcal infections are not uncommon,<sup>1</sup> but the attention directed to the respiratory phase of such infections is very scant. In view of the uniqueness of one of the cases observed and because of the lack of recent literature on the subject, it seemed worth while to report the cases and briefly to review the literature. The fact that most of the cases previously reported involved military personnel in World War I also affords an opportunity to review similar experience in World War II.

## CASE REPORTS

P. C. (B.C.H. 1088509) a 56-year-old man entered the hospital on November 24, 1942 because of chills and fever, cough and vague chest pain of 4 days duration. Physical examination revealed moist rales in the right axilla and a roentgenogram on the day of admission was reported as showing pneumonia of the right middle lobe. A blood culture taken before exhibition of sulfadiazine revealed a growth of Type 1 meningococcus. Neufeld typing of the sputum was reported as negative.

On sulfadiazine therapy from November 24 to 30 the patient made an uneventful recovery. A repeat x-ray film on December 3 was reported as being within normal limits. The white-cell count dropped from 14,100 on entry to 9,150. Blood cultures on November 29 and December 7 revealed no growth and the patient was discharged on December 10.

In this case of pneumonia routine blood cultures showed a growth of Type 1 meningococcus. Since Neufeld typing of the sputum was negative for both the pneumococcus and the meningococcus the evidence that the pneumonia was meningococcal in origin is indirect but warrants attention. The response to sulfadiazine was characteristic of that expected in either pneumococcal or meningococcal infections and did not resemble the response of pneumonias of virus etiology.

L. L. (B.C.H. Case 1090910†) a 33-year-old haker's helper was admitted to the hospital on December 21, 1942 with complaints of pain in the left side of the chest of 3 days duration, hemoptysis of 3 days duration and rash on the legs of 1 day's duration. For the past 2 weeks the patient had a "heavy" cough and had expectorated slight amounts of mucoid sputum which was occasionally blood streaked. Although not feeling too well, he had been able to work "heavily" every day. However 3 days prior to admission he noticed a sharp pain in the left maxillary region accompanied on deep breathing and coughing. Expectoration of

thick rusty sputum was noted on the same day. The symptoms became increasingly severe. On the day before admission a chill and fever were noted and, for the first time a red rash was seen on both lower extremities. The skin lesions were not painful, itchy or raised above the skin surface. The patient denied any previous similar manifestations.

The patient was unmarried and had been on relief for many years. He was a known chronic alcoholic of many years' standing. At the age of 20 he had had a penile sore and had been told that he had had blood many years before the present episode.

In January 1938 he had been seen in the Outpatient Department for shortness of breath. A positive blood Hinton test was noted. Physical examination showed an aortic diastolic murmur and the diagnoses of late latent syphilis, syphilitic heart disease with aortic regurgitation and generalized arteriosclerosis were entered in the record. A 7 foot roentgenogram of the chest revealed widening of the ascending and descending aorta raising the question of aortic aneurysm. After a few intramuscular injections of bismuth in oil had been given the patient absented himself from the clinic.

Physical examination disclosed a markedly dyspneic poorly nourished man who grunted with every respiration. The face was flushed, and dilatation of the alae nasi was noted. Over the thighs, feet and legs there was a petechial rash the lesions being pin point to 3 mm. in diameter, some were discrete and others confluent and did not blanch on pressure. The teeth were in very poor condition but the gums were firm and no bleeding was noted. The neck was supple, and Kernig and Brudzinski signs were absent. Examination of the chest revealed limitation of respiratory excursions of the left hemithorax. Decreased tactile fremitus, marked diminution of breath and voice sounds and dullness on percussion were noted over the lower half of the left portion of the chest, extending up to the level of the third rib anteriorly and the fifth thoracic vertebra posteriorly. The trachea was deviated to the right. The apical impulse was not made out on palpation; there was sinus rhythm with a rate of 100 per minute, and no aortic diastolic murmur was heard best in the third left interspace. Neurologic examination was not remarkable. The patient was somewhat incoherent and confused but cooperative and euphoric.

The temperature was 101.8 F., the pulse 118 and the respirations 34. The blood pressure was 130/100.

Examination of the blood demonstrated 110 gm. of hemoglobin and a white-cell count of 8950 with 84 per cent neutrophils and 17 per cent lymphocytes. The hematocrit was 36 per cent and the corrected erythrocyte sedimentation rate 35 mm. in 1 hour.

The sputum was thick, rusty and tenacious. Gram's stain revealed the sputum to be loaded with gram negative diplococci, the polymorphonuclear cells burst with these gram negative diplococci which had the morphology of meningococci. A number of gram positive diplococci outside the polymorphonuclear cells were also noted. Neufeld typing and culture revealed predominantly Type 1 meningococci with some Type 15 pneumococci.

A roentgenogram confirmed the impression that fluid was present in the left side of the chest. Thoracentesis was productive of 1250 cc. of serousanguinous fluid which contained 4500 leukocytes per cubic millimeter, 95 per cent of which were polymorphonuclear cells. Culture of this chest fluid on blood agar plates was positive for gram negative diplococci which were typed as Type 1 meningococci.

Blood cultures on admission before institution of chemotherapy and on the 3rd and 13th hospital days were negative for the meningococcus. Urinalyses were not remarkable, and there was a positive blood Hinton test but negative spinal-fluid Hinton and Wassermann tests. The spinal-fluid examinations, including culture, were not remarkable.

\*From the Fifth and Sixth Medical Services (Boston University) Boston City Hospital.

†Instructor in medicine, Department of Medicine, Georgetown University School of Medicine, formerly resident, Fifth and Sixth Medical Services, Boston City Hospital.

The bacterial seed studies in this case were made in the laboratory of Dr. Maxwell Finland, at the Thorndike Memorial Laboratory, Boston City Hospital.

The patient was given 5 gm of sodium sulfadiazine intravenously on admission and in the usual oral dosage, adequate blood levels were obtained. Rumpke-Leede's test on the day of admission and on several subsequent days was negative for petechiae. The rash on the legs began to fade on the 2nd hospital day and had completely disappeared 5 days later. The sputum and chest fluid on the 3rd hospital day, as well as on subsequent examinations, were negative on culture for the meningococcus. It was apparent that a unique extrameningeal meningococcal infection, causing pneumonia, pleurisy with effusion and skin rash, was involved.

For the first 5 hospital days, the patient improved remarkably, and the signs in the left side of the chest appeared to be clearing. The bacteriologic studies and clinical course were convincing evidence that sulfadiazine was controlling the infectious process. At no time were signs of meningeal involvement present.

On the evening of the 5th day the patient became suddenly cyanotic and dyspneic, frothy pink sputum being expectorated. This typical attack of pulmonary edema was controlled by the use of intranasal oxygen and intravenous aminophylline. The patient was digitalized with moderate speed. A vital-capacity determination on the 8th hospital day was 30 per cent of normal.

In the remaining 7 hospital days the problem was essentially one of treating acute left ventricular failure. There were repeated bouts of pulmonary edema, dyspnea and cyanosis. The patient during this period was hallucinated and at times maniacal, requiring marked restraint and sedation. In spite of all the usual methods of therapy, he died on the 13th hospital day during one of these episodes.

Autopsy was performed 15 days post mortem (the interval after death precluded definitive bacteriologic study). Cardiac failure was thought to be the cause of death, as evidenced by pulmonary congestion and edema, chronic passive congestion of the liver and congestion of the spleen and kidneys. The left lung showed an organized confluent bronchopneumonia. The heart revealed severe coronary-artery atherosclerosis, with calcification and dilatation of the ascending aorta. Histologic study did not confirm the clinical impression of syphilitic aortitis or valvulitis.

In this case meningococcal pneumonia and pleural effusion were present without meningeal involvement. The patient did well on chemotherapy so far as the infective process was concerned but, as autopsy showed, died of heart disease. The post-mortem finding of a confluent bronchopneumonia was also reported in the autopsy material of Fletcher.<sup>2</sup>

### DISCUSSION

Osler<sup>3</sup> and others have pointed out that pneumonia is frequently described in certain outbreaks of epidemic meningitis, but the etiology of these pneumonias is not clear. The first recorded cases of primary meningococcal pneumonia were those of Jacobitz,<sup>4</sup> who reported 12 patients among a company of soldiers infected by the meningococcus. He divided the cases into five groups: typical meningococcal meningitis (2 cases), meningococcal pneumonia in association with meningitis (3 cases), pneumonia without meningitis (in a case in which sputum and nasopharyngeal examinations revealed meningococci and the symptoms included pyrexia ending by crisis, rusty sputum and signs of consolidation), bronchial catarrh without meningitis, the sputum containing meningococci (4 cases), and lung infections in which the meningococcus was found mixed with other bacteria (2 cases).

Sophian<sup>5</sup> mentioned a case in the 1912 Kansas City meningitis epidemic of a woman who had pneumonia

and was treated for four days, during which many meningococci were present in the sputum. She then developed meningococcal meningitis.

Osler<sup>3</sup> reported that 8 cases of pneumonia occurred in a Boston epidemic of cerebrospinal fever, but he did not give the bacteriologic findings.

During the influenza epidemic of 1918-1919, impetus to the study of meningococcal pneumonia occurred because of the complicating bronchopneumonias. This was especially true among American troops in England and France. Fletcher<sup>2</sup> reported the bacteriologic findings in post-mortem examinations of 36 patients who had died from bronchopneumonia following influenza contracted on a transport ship from the United States. In 11 cases the meningococcus was the predominant organism, but in each case *Haemophilus influenzae* was also present. Kinnicutt and Binger<sup>6</sup> found at autopsies in 47 cases of postinfluenzal bronchopneumonia at a base hospital in France that lung cultures were positive for the meningococcus in 19. It is also interesting to note that in 50 cases of bronchopneumonia in which blood cultures were taken, 10 per cent revealed growth of meningococci and terminated fatally. Meader, Means and Hopkins,<sup>7</sup> reporting on American troops in England, observed 5 cases of meningococcal pneumonia among 188 cases in which lung cultures were done at autopsy.

Probably the most complete work on this subject was done by Holm and Davison<sup>8</sup> and Davison, Holm and Emmons.<sup>9</sup> At a camp in France they studied 403 cases of pneumonia, many of which—but not all—were postinfluenzal pneumonias. Of these cases, 85 showed meningococci in the sputum. Of the 78 patients who died of pneumonia and were studied by culture at autopsy, 23 revealed meningococci in the lungs. Of these, 7 gave pure and 16 gave mixed cultures. From the studies, it was concluded that the meningococci may produce either bronchopneumonia or lobar pneumonia and that, because of the similarity of the organisms found in these cases to those found in the spinal fluids of patients with meningococcal meningitis, cases of meningococcal pneumonia may arise from cases of meningococcal meningitis and vice versa.

Reimann<sup>10</sup> states that the pleura is seldom involved in cases of meningococcal pneumonia. The cases reported in the literature substantiate this statement. The only case, other than the one recorded above, in the available literature was reported by Herrick<sup>1</sup> in a soldier who had bronchitis and later developed pleurisy with effusion and empyema. Culture of the aspirated chest fluid revealed a growth of meningococci.

The great majority of the cases of meningococcal pulmonary infection in World War I were associated with the complicating pneumonias of the severe influenza epidemic then prevalent. During World War II the severe pandemic type of influenza did not occur, although scattered, milder epidemics

were occasionally reported. It is therefore quite interesting that the only pertinent paper found in a review of the available literature since the onset of World War II was that of Roberg,<sup>11</sup> who reported a case in which a severe meningococcal pneumonia developed five weeks after recovery from pneumonia, probably of viral etiology. In this case the sputum smear showed gram-negative intracellular diplococci and the sputum culture revealed 75 per cent meningococci and 25 per cent hemolytic streptococci (Group A). A blood culture taken prior to sulfadiazine therapy was negative. The patient had a morbilliform rash. Roberg indicates that if the sputums in cases of pneumonia were routinely cultured under conditions favorable to the growth of the meningococcus, recognition of meningococcal respiratory infection would be made more frequently than is indicated by the paucity of reference to this entity in the literature.

#### SUMMARY

A case of meningococcal pneumonia with meningococcal pleural effusion is presented, and the literature reviewed.

### CLINICAL NOTE

#### AN UNUSUAL COMPLICATION OF INTESTINAL INTUBATION\*

MAJOR ADDISON G. BRENIKER, JR., M.C., A.U.S.

THE value of intestinal intubation for decompression by suction is so widely recognized that it is used extensively as a diagnostic and therapeutic adjunct. The Miller-Abbott and similar tubes, however, require the same working precision as any other instrument, and their proper function needs the attending physician's constant care to prevent complications.<sup>1,2</sup>

Most of the complications are familiar to all who have employed intestinal intubation. None are so serious as to condemn wide use of the procedure, but all are to be avoided if possible. The following is a list of minor hazards, some of which may seriously interfere with satisfactory decompression: difficulty or inability to introduce tubes into the duodenum<sup>1-3</sup>; minor epistaxis, transient pharyngitis or eustachian salpingitis, leaking or transposed adapters, leaking or ruptured balloons, leaking tubing, coiling in the stomach<sup>4,5</sup>; blocking of the suction lumen with intestinal contents, and accumulation of secretions proximally.

Other reported complications, such as acute otitis media, laryngeal edema or necrosis,<sup>6</sup> gastrointestinal

In epidemics of meningococcal infection with or without meningeal involvement, careful bacteriologic studies will probably uncover more cases of meningococcal pulmonary involvement than are reported at present.

hemorrhage,<sup>7</sup> perforations, obstruction or intussusception from overdistended balloons<sup>8</sup> and knotting of the tubing distal to the gastric cardia,<sup>9,10</sup> may seriously endanger a patient's life, even when promptly treated and may necessitate additional surgery at a most inopportune time.

The following recently encountered case is illustrative of a complication that is of interest because of its unusual character and the fact that a few simple precautions may prevent its occurrence.

A 17-year-old soldier was admitted to hospital on February 19, 1947, with the typical history and physical findings of acute appendicitis of 24 hours duration. At operation a gangrenous appendix, which was perforated, no removal was found. In spite of parenteral antibiotics and Ochsner treatment a generalized peritonitis developed. On the 5th day a pelvic abscess was noted on rectal examination. Although greatly doze palpation apparently caused intraperitoneal rupture of the abscess, which was successfully drained through the rectum 4 days later. A subhepatic abscess, which subsequently localized, was drained on the 12th day after appendectomy.

On an attempt to begin oral feeding on the 13th day the patient developed abdominal cramps, nausea, vomiting, distention and obstipation. Roentgenograms of the abdomen showed dilated small intestine patterns with dependent fluid levels. A Miller-Abbott tube with 2 cc. of mercury in the balloon<sup>1</sup> was passed into the stomach and attached to constant suction. After repeated unsuccessful attempts the tube finally passed through the pylorus spontaneously on the 5th day. Fortunately during this period decompression progressed satisfactorily with intragastric suction; the patient remained afebrile, was relieved of pain and maintained a slow pulse and the abdomen remained nontender.

In the next 48 hours the tube progressed rapidly to a point in the left lower quadrant from which it moved slowly if at all. Five days after passage beyond the pylorus the 3 foot mark had not reached the external nares. Under fluoroscopic observation thin barium sulfate suspension was introduced to determine the site and extent of the obstruction.<sup>1</sup> The barium was seen to pass very slowly through a 5-cm. seg-

\*From the Surgical Service, Tilton General Hospital, Fort Dix, New Jersey.

ment of jejunum whose lumen was persistently constricted to 3 or 4 mm and thence into normal bowel. However, the most remarkable finding was that just proximal to this obstruction the tube was tightly coiled through two full turns into which the distal end had passed to make a simple (straight) knot. An attempt was made to withdraw enough tube to uncoil its distal end, and traction to the point of pain was made. This resulted in straightening of the normal curves at the gastric cardia, duodenum and ligament of Treitz but failed to move the coiled, distal end.

Since the point of obstruction had been demonstrated, and the patient had been decompressed, adequately hydrated and was in good electrolyte balance, immediate operation was performed. The abdomen was opened through a left paramedian incision, and an obstructing omental adhesive band was

FIGURE 1 Film Showing Conclusively the Presence of Two Complete Coils about the Mercury-Weighted Balloon

readily located about 4 feet distal to the ligament of Treitz. The tube was found to be tightly coiled and knotted proximal to this point, but it was possible to untie the knot and withdraw the tube without opening the bowel. The patient subsequently made an uneventful recovery.

### DISCUSSION

Looping and coiling of intestinal tubes in the stomach is very commonplace, and the practice of feeding excess lengths of tubing into the stomach without frequent radiologic check-up is universally condemned.<sup>5</sup> On the other hand coiling or knotting of tubing in the lumen of the small intestine is most unusual, particularly in the absence of redundant loops behind the advancing tip. To produce such a

complication there apparently must be dilated bowel proximal to a nearly complete obstruction, hyperactive peristalsis and a tube that is quite flexible or has previously been deformed by storage in a tight coil.

The tube used in the case reported above was not new, was moderately flexible and was found to have been stored in a tight coil for a considerable length of time. The use of a mercury-weighted balloon probably carried the tip to the point of obstruction more rapidly<sup>5</sup> than the rate of proximal decompression and may have played an indirect role in the coiling process. The weight of mercury in the balloon apparently caused the tip of the tube to prolapse through the coils (Fig 1) and produce a straight knot, which was tightened when extraction was attempted. Therefore, it seems reasonable to call attention to this possibility of coiling at an obstructed point with the use of the Harris single-lumen, mercury-weighted rubber tube<sup>5</sup> or the even more flexible, nonopaque, single-lumen "Koroseal" tubing described by Millet.<sup>7</sup>

It seems likely that this complication may be prevented by the following precautions: storage of all types of intestinal tubing in broad loops or, preferably, in linear fashion by vertical suspension, avoidance of introducing redundant loops of tubing without repeated radiologic check on the progress of the tip, and demonstration of the site and relief of obstruction as soon as practicable after the forward progress of the tip definitely stops.

### SUMMARY

The more frequent complications of intestinal intubation are considered.

A case is presented in which a mercury-weighted Miller-Abbott tube spontaneously coiled and tied itself into a simple knot in the jejunum proximal to an obstructing omental adhesion. This complication was apparently produced by the use of a flexible tube, previously deformed by long storage in a tight coil.

Ideally, intestinal tubes should maintain slight inflexibility and should be stored without coiling deformity, and their progress through the intestine should be followed carefully by x-ray observations.

## THE SIGNIFICANCE OF "TICS" AS POSSIBLE MANIFESTATIONS OF EPILEPSY\*

SIDNEY LEVIN, M.D.†

BOSTON

IN DESCRIBING the numerous manifestations of epilepsy, recent textbooks of neurology<sup>1-3</sup> discuss a great variety of motor phenomena but do not include the so-called "tics" as possible manifestations of epileptic disorder. However, in the older literature<sup>4-6</sup> the coexistence of epilepsy and tic was noted frequently enough to raise the question of an etiologic relation between the two, although conclusions regarding such a relation were generally believed to be premature. With the introduction of electroencephalography a new technic has become available, promoting a broader knowledge of epilepsy and permitting a re-evaluation of questions concerning epileptic manifestations. During the past two years I have observed 3 cases of tic in which, with the aid of electroencephalographic study, a diagnosis of epilepsy was made and in which, on the basis of all the evidence available, it appeared that the tics were true manifestations of epilepsy and not unrelated findings.

## CASE REPORTS

**CASE 1.** A 12-year-old boy was first seen on May 18, 1946, having been referred for treatment of a facial tic, which had been present for approximately 1 year and was considered a psychoneurotic manifestation.

The past history revealed that from the age of 6 years the patient had displayed several other types of motor phenomena (interpreted as "nervous habits") as follows: brief opening and closing of both fists, brief jerk of the head to one side with immediate return to the midline, sudden opening and closing of the mouth and sudden wrinkling of the forehead. Each type of motor pattern occurred several times daily for a few months and was then replaced by one of the others.

The patient was considered intelligent and was doing well in the 7th grade of school. There was no history of serious illnesses. The family history revealed that the patient's father had epilepsy; his attacks were of the grand mal type and had occurred about once every 2 years since the age of 15.

On neurologic examination the only positive finding was the occurrence of brief twitching of the orbicularis oculi muscles primarily on the right side occurring every few seconds. The patient was co-operative but seemed slightly embarrassed during the examination.

An electroencephalogram<sup>7</sup> showed a great deal of slow-wave activity with marked shifting asymmetry. There were definite discharges of typical 3 per-second spike and wave activity at rest and these were greatly exaggerated during overbreathing.

On treatment with 90 mg. of Mebaral twice daily the tic completely disappeared and there were no unpleasant side effects of this medication. When the therapy was changed to tridione the twitching occurred more frequently than prior to the first visit. Therefore the patient was maintained on 90 mg. of Mebaral twice daily with control of twitching until the last examination 1 year later. Shortly before the last examination experimental withdrawal of Mebaral was followed by a return of the tic within 48 hours.

However when the drug was readministered, there was again complete control.

**CASE 2.** A 9-year-old boy was first seen on August 1, 1946, because of a "facial tic" of 1 year's duration. Prior to his visit the patient had consulted an oculist because it was thought that he required glasses; the eyes were found to be normal, and he was then referred for psychiatric study.

The past history revealed that at the age of 1 year the patient had had a generalized convulsion and had been hospitalized for 4 days. A diagnosis of acute tonsillitis was made at that time. There were no other generalized convulsions up to the time of his first visit.

The patient had recently completed the 3rd grade of school with high marks. Although his behavior was described as satisfactory it had been observed that he was at times, slightly irritable.

Neurologic examination was negative except for the occurrence of brief twitching of the orbicularis oculi muscles every few seconds. The patient was co-operative and friendly; he was not shy or fearful.

An electroencephalogram showed a great deal of high-voltage slow wave activity in the frequency range of 4 to 7 per second occurring in groups and also as scattered waves. During overbreathing there was a very large build up with the occurrence of episodic high voltage 3 per-second waves but no spikes. Although the tracing was suggestive of petit mal activity there were no typical petit mal waves.

Treatment was started with 30 mg. of phenobarbital three times daily. One week later the patient showed marked improvement, no twitching of the orbicularis oculi muscles was observed. However further study was not possible because the mother was unwilling to have her son take regular medication.

**CASE 3.** A 14-year-old boy was first seen at the Southard Clinic on March 13, 1946, because of a history of repeated twitching of the head of 1 year's duration. Several times daily the patient's head jerked slightly to the right and then promptly returned to the midline.

The patient had been a behavior problem since the age of 5. He was a oaf hater, was at times stubborn, rude or disagreeable and frequently disobeyed his parents, 2 weeks before entry he had been arrested with a group of boys for breaking into a store. However he was doing well in the 9th grade of school.

Neurologic examination was negative except for the appearance of an occasional slight twitch of the head to the right with a rapid return to the midline. During the interview the patient was somewhat evasive and seemed resentful at having been brought to a psychiatrist for examination.

The electroencephalogram showed paroxysmal high voltage discharges occurring at rest. On overbreathing there was a large build up, with the appearance of numerous high voltage 3 per-second waves some associated with small spikes. The tracing was consistent with epileptic disorder of the petit mal variety.

The patient was given 90 mg. of Dilantin Sodium three times daily, and after a few days the so-called "tic" disappeared. Three months later the medication was discontinued and during the subsequent 4 months of follow up observation there was no recurrence of twitching.

## DISCUSSION

In all 3 cases presented above the electroencephalograms showed epileptic dysrhythmias. In 1 case the electroencephalogram revealed classic bursts of 3-per-second spike and wave activity, diagnostic for the petit-mal epilepsies. In another case bursts of 3-per-second waves with small spikes occurred,

\*From the Boston Psychopathic Hospital and the Department of Psychiatry, Harvard Medical School.

†Assistant in psychiatry, Harvard Medical School; assistant physician, Boston Psychopathic Hospital.

Electroencephalograms were recorded at the Boston Psychopathic Hospital and were interpreted by Dr. Milton Greenblatt.

although not classic, this tracing was also considered characteristic for petit-mal epilepsy. In the third case, although the dysrhythmia was of the high-voltage, slow-wave, 3-per-second variety, the absence of spikes made the tracing only suggestive of petit-mal dysrhythmia. However, when all three electroencephalograms were viewed together one obtained the impression that they represented similar dysfunctions. In each case a diagnosis of idiopathic epilepsy was made.

It is my opinion that these 3 cases represent atypical forms of myoclonic epilepsy. In favor of this opinion is the electroencephalographic finding of 3-per-second spike and wave dysrhythmia, which, according to Lennox,<sup>7</sup> is characteristic of myoclonic epilepsy as well as of petit-mal and akinetic epilepsy. Tics have a resemblance to myoclonic jerks, and although in the usual forms of myoclonic epilepsy brief contractions of muscles in the upper extremities occur, at times similar contractions of other muscles are seen.<sup>7</sup>

Tics are usually considered to be manifestations of neurotic disorders.<sup>8</sup> One should therefore consider the possibility that the tics in these cases were of psychogenic etiology and that their occurrence in patients with epileptic dysrhythmia was merely a coincidence. This possibility cannot be entirely excluded with the limited evidence available. However, it appears to be more likely that the tics described were true manifestations of epilepsy, not only in view of their resemblance to myoclonic phenomena and the rather characteristic electroencephalographic findings but also because of the pronounced response to relatively small doses of anticonvulsant medication without the appearance of drowsiness or other side effects.

Wechsler<sup>2</sup> states that, although most observers have assumed tics to be psychogenic, the fact that they occur at times on the basis of brain damage—for example, as a sequel to epidemic encephalitis—should lead one to question routine psychogenic explanations of their origin. He states that the precipitation or aggravation of tics by emotional factors does not argue in favor of a completely psychogenic explanation because many definitely “organic” movements are similarly affected by emotional fluctuations.

In view of these considerations it appears reasonable that more cases with tics should be studied from the electroencephalographic point of view to clarify the question whether there is an underlying epileptic dysrhythmia. Although it is expected that few such patients will be found to have epilepsy, this diagnosis should be kept in mind when the problem of tic presents itself.

#### SUMMARY

Three cases are reported in which tics appeared to be manifestations of epilepsy. It is suggested that more cases with tics be studied by electroencephalography to determine the incidence of epileptic dysrhythmia in this group of disorders.

## INFECTIOUS MONONUCLEOSIS WITH INTENSE JAUNDICE OF LONG DURATION\*

HERBERT L. ABRAMS, M.D.†

BROOKLYN, NEW YORK

**J**AUNDICE in infectious mononucleosis was first described in 1923 by Downey and McKimlin.<sup>1</sup> Since that time, scattered reports of its occurrence have appeared.<sup>2-21</sup> Martin,<sup>8</sup> in 1941 described 13 previously reported cases. In 1944 Boger<sup>17</sup> found 27 cases, and Spring,<sup>14</sup> in the same year, estimated that 35 cases had been recorded. Wechsler<sup>21</sup> discovered an additional 25 cases and reported 34 cases of his own from an epidemic of infectious mononucleosis. Thus, at least 100 cases have been described. This figure is in no sense an adequate reflection of the frequency of clinical jaundice in infectious mononucleosis, since undoubtedly many cases remain unreported. In different series, the incidence of jaundice has ranged from 0 to 13 per cent.<sup>1, 11, 19-21</sup>

The following case is presented because of the extreme severity of the hepatic involvement.

## CASE REPORT

**F**G., a 30-year-old man entered the hospital complaining of jaundice of 3 weeks duration. Five weeks before admission he had noted the onset of anorexia. One week later the urine became dark, and he began to experience easy fatigability and weakness. Three weeks before admission the skin became yellow and the stools light. He had no abdominal pain throughout this period but lost 30 pounds in weight. During the week before admission pruritus became pronounced. He had had a low-grade temperature for a few weeks and bad sensations of chilliness and generalized mild aches. The remainder of the history was inconsequential.

Physical examination disclosed a large-framed muscular markedly jaundiced man in no acute distress. A few petechiae and ecchymoses were present on the upper anterior portion of the chest wall. In the axillary and inguinal regions bilaterally small lymph nodes 1-2 cm in diameter were palpable. No cervical or epitrochlear nodes were felt. Examination of the chest was negative. The liver edge was palpated 2 cm below the costal margin and was nontender. The splenic edge was 2 cm below the costal margin and firm in consistency. The remainder of the examination was negative.

The temperature was 101°F. Examination of the blood revealed a hemoglobin of 12.5 gm per 100 cc. and a white-cell count of 4500 with 21 per cent neutrophils, 54 per cent lymphocytes, 15 per cent monocytes, 5 per cent eosinophils, 1 per cent basophils, and 4 per cent stab cells. Many of the lymphocytes had foamy vacuolated cytoplasm, kidney bean and clover shaped nuclei. Increased azurophilic granulation and "folding-over" of the cytoplasm. The heterophil-antibody test was negative at that time although the patient had been ill for 5 weeks.

The icteric index was 210, and the van den Bergh reaction immediate direct and indirect, with a bilirubin of 20.0 mg per 100 cc. The alkaline phosphatase was 4 units, the cholesterol 149 mg per 100 cc., with only a trace of esters, and the cephalin-flocculation test was negative. The total protein was 5.4 gm per 100 cc., with an albumin of 3.6 gm and a globulin of 1.8 gm. A stool was negative for bile. The urine was positive for bile but negative for urobilinogen. The prothrombin was 80 per cent of normal and the bleeding time was 2 minutes. On the intravenous hippuric acid test 0.42 gm was excreted in 1 hour (normal 0.8-1.3 gm).

X-ray study of the abdomen showed hepatomegaly and splenomegaly. There was no evidence of gall-bladder calculi.

Four days after admission the serum bilirubin rose to 27.5 mg per 100 cc. and a ++ cephalin flocculation test, which subsequently became +++ developed. Thereafter the icteric index began gradually to decrease. Bile appeared in the stool and urobilinogen in the urine. The icteric index dropped from 210 to 171 a week after admission to 61 within 2½ weeks of admission to 43 a week later and to 31 during the 5th and 7th during the 6th hospital week, and to 18 4 days before discharge. The hospital stay was 8 weeks.

During the first 3 weeks the temperature never rose above 102 F. and thereafter the level gradually returned to normal. Treatment consisted of a high-calorie, high protein, high carbohydrate low-fat diet, with added vitamins and lipotropic factors, and on this regimen appetite improved and the patient felt much better. No significant adenopathy developed. The liver and spleen remained palpable for about 6 weeks and were not felt thereafter. The total protein rose to 6.1 gm per 100 cc. and the albumin to 4.3 gm. The cholesterol reached 194 mg. and the cholesterol esters 82 mg per 100 cc.

A marked leukopenia was present throughout, the white cell count dropping to 2900 a week after admission and to 2000 on the following day. It remained below 5000 for about 7 weeks, reaching 5200 during the week before discharge. The peak of the lymphocyte percentage was 78 per cent, which was present 1 week after admission; the level thereafter gradually decreased until it reached 31 per cent the week before discharge.

Initially the heterophil-antibody test was negative. Two and a half weeks after admission a positive titer of 1:28 was reported, a week later the titer had risen to 1:112 and in the fifth week it rose to 1:896. At the time of discharge, the patient was faintly icteric, but otherwise well.

## DISCUSSION

Kulham and Steigman<sup>9</sup> have described an acute focal hepatitis with histiocytic reaction in infectious mononucleosis, and Ziegler,<sup>22</sup> has confirmed the presence of an acute inflammatory liver reaction. Cohn and Lidman<sup>23</sup> reported hepatic involvement, as judged by different liver-function tests, in 15 successive cases of infectious mononucleosis without jaundice.

Among 64 patients with infectious mononucleosis seen at the Long Island College Hospital during the past ten years, 6, or 9.4 per cent, showed jaundice clinically. The cephalin-flocculation test was performed on 25 of these patients, and was ++++ in 11 patients (44 per cent), +++ in 2 (8 per cent), ++ in 4 (16 per cent), + in 2 (eight per cent), doubtful in 2 (8 per cent) and negative in 4 (16 per cent). Thus, it was definitely positive in 52 per cent of cases and questionably positive in an additional 22 per cent. This suggests that a far greater number of patients with infectious mononucleosis have liver damage than the presence of clinical jaundice indicates, although it is known that other conditions than liver disease may cause a positive test.

The patient described above was visibly icteric for at least eleven weeks. The duration of the ill-

\*From the Medical Service, Long Island College Hospital.  
†Assistant resident, Department of Medicine, Montefiore Hospital, New York City, formerly intern, Department of Medicine, Long Island College Hospital.

ness, including the preicteric period, was thirteen weeks. He failed to develop a definitely positive Paul-Bunnell test until eight and a half weeks after the onset of the illness. The jaundice appeared initially to be obstructive in character, and yet there was definite evidence of an active hepatitis (the cephalin-flocculation test, the hippuric acid test and the ratio of cholesterol to cholesterol esters). The intensity of the hepatitis may have been linked to the late development of the usual serologic response to infectious mononucleosis. Thus, the possibility of a diminished immunologic defense mechanism must be considered. Although the presence of enlarged lymph nodes in the hilus of the liver could not be ruled out, there was sufficient evidence of acute hepatitis to establish this as the most probable cause of the jaundice.

Most cases of jaundice in infectious mononucleosis have been of short duration and slight intensity. Downey and McKinlay's<sup>1</sup> case in 1923 had a "faint and transient" jaundice. In the case reported by Fowler and Tidrick,<sup>6</sup> the jaundice disappeared in eight days. Martin,<sup>8</sup> reviewing the literature before 1941, stated that the jaundice seldom lasted longer than a week. Contratto<sup>13</sup> reported that the usual duration of icterus was not more than two weeks. In the 5 cases reported by Spring,<sup>14</sup> the jaundice lasted no longer than two and a half weeks. Kruger's<sup>19</sup> patient remained icteric for three weeks. Wechsler<sup>21</sup> found that three and a half weeks was the average duration of icterus in his 34 patients, 3 of whom remained icteric for over forty days. The longest duration of jaundice reported was 48 days.<sup>21</sup> None of the 6 cases studied at the Long Island College Hospital exceeded ten days in duration, with the exception of the case reported above.

Laboratory data reflecting the intensity of the jaundice were rarely presented. Wakefield and Mackay<sup>2</sup> found the bilirubin to be 5.6 mg per 100 cc, and in Fowler's<sup>6</sup> case it was 5.0 mg. The highest figures cited by Bernstein<sup>7</sup> in a comprehensive review of infectious mononucleosis in 1940, were an icteric index of 50 and bilirubin of 8 mg per 100 cc in the case described by Stuart, Burgess et al.<sup>3</sup> in 1934. The same figures were mentioned by Wintrobe<sup>25</sup> in 1942. Kilham and Steigman<sup>9</sup> reported 4 cases in 1942 in which the highest bilirubin was 7.5 mg per 100 cc. In the same year, Carter<sup>10</sup> observed a case in which the bilirubin was 22.0 mg per 100 cc, and Gold<sup>11</sup> described one with a bilirubin of 23.3 mg and an icteric index of 150 units. The highest figures in Spring's<sup>14</sup> cases were an icteric index of 74.3 and a bilirubin of 7.0 mg per 100 cc. In the cases reported by Monat,<sup>15</sup> Boger,<sup>17</sup> and Morris<sup>18</sup> the highest icteric index was 81. Wechsler<sup>21</sup> found 100 to be the highest icteric index in his cases, only 2 patients having levels over 80. The highest icteric index in

the group of cases at the Long Island College Hospital was 31 (except for the patient described above).

Thus, the jaundice of infectious mononucleosis has usually been mild, and its duration has rarely exceeded a month. In the case reported above the jaundice not only exceeded that of Gold's patient in intensity — the icteric index reaching 210 and the bilirubin 27.5 mg per 100 cc — but also lasted almost twice as many days as that in the longest case described. This case represents an extraordinary degree of hepatic involvement in infectious mononucleosis, no parallel for which has been found in the literature reviewed.

The profound leukopenia may have been related to the hepatic damage. Leukopenia is not uncommon during the first week of infectious mononucleosis, but usually the white-cell count rises before the temperature returns to normal.<sup>25</sup> Press<sup>20</sup> found leukopenia during the first week in 38 of 96 patients, during the second week, however, the white-cell count was normal or above in most cases. In the case presented above the white-cell count not only reached 2000 during the fifth week of jaundice but also remained below 5000 during the first seven weeks of hospitalization.

It should be pointed out that this case resembled a severe case of infectious hepatitis in all respects except the peripheral blood smear. The negative Paul-Bunnell tests during the first eight weeks of the illness might well have been accepted as evidence that this was, indeed, a case of infectious hepatitis, especially in view of the frequent occurrence of lymphocytosis and atypical lymphocytes in infectious hepatitis. The importance of repeated heterophil-antibody tests for long periods in suspected cases cannot be overemphasized. Probably many cases that failed to show the specific serologic response early in the disease have been labeled infectious hepatitis, when they actually represented one of the protean manifestations of infectious mononucleosis.

The therapy of infectious mononucleosis should be revised in the light of present knowledge of the frequency of liver involvement. Dietary therapy should be similar to that in infectious hepatitis, with a high-calorie, high-protein, high-carbohydrate diet. The early ambulation commonly allowed should be restricted in many cases. Certainly, bed rest should not be discontinued until laboratory evidence of hepatic involvement has disappeared. The experience of some patients, who have a long period of weakness and malaise after the illness is apparently at an end, might thus be avoided, and the possibility of recurrence or of permanent hepatic damage would be diminished.

#### SUMMARY

A case of infectious mononucleosis with intense jaundice of long duration is presented. The literature is briefly reviewed.

Of 64 cases of infectious mononucleosis at the Long Island College Hospital, 6, or 9.6 per cent, showed clinical jaundice. The cephalin-flocculation was strongly positive in 13 of 25 patients (52 per cent) on whom it was performed and questionably positive in 6 (22 per cent).

It is suggested that in doubtful cases in which jaundice is present, repeated heterophil-antibody tests be performed before infectious mononucleosis is ruled out.

Dietary therapy and bed rest are important in the management of infectious mononucleosis.

## MEDICAL PROGRESS

### UROLOGY

FLETCHER H. COLBY, M.D.\*

BOSTON

THE most frequent conditions treated by the urologist are those of the prostate and bladder. With the increased life expectancy that has taken place during the past twenty years, many more men reach the age when prostatic enlargement is likely to occur. The treatment of the obstructing prostate, therefore, deserves increasing consideration. Carcinoma of the bladder has always been a difficult problem, and its treatment in the past has not been too satisfactory. Some progress has been made in the understanding and treatment of both these diseases.

#### Retropublic Prostatectomy

Two years ago an entirely new procedure for the relief of prostatic obstruction was described by Millin,<sup>1</sup> of London. This operation is called retropublic prostatectomy and the author believes it to be original although a similar approach was used by van Stockum<sup>2</sup> in 1909.

The features of the operation as described by Millin are as follows: it is an extravesical procedure, it is applicable to all types of prostatic obstruction, it is relatively short and free of shock, the anatomic

approach to the prostate is a reasonable one, since no important structures are endangered, the mortality is low, the postoperative course is better (the postoperative stay in the hospital is seldom over two weeks), and all obstructing tissue is removed.

In a discussion of other recognized operations for the prostatic Millin made the following comparison:

**Suprapubic operations.** These operations require 6 to 10 per cent and involve a long stay in comfortable convalescence. There is considerable blood loss during and after operation. Postoperative infection is high. There is a high incidence of secondary hemorrhage.

**Perineal operations.** Technical difficulties require a long period of preparation for the danger of urinary incontinence, damage to the rectum and persistent fistulas is great. No cure is difficult because of wound contamination from the rectum.

**Transurethral operations.** It is difficult to learn to do these operations efficiently. A considerable blood is lost when large glands are moved. Persistent postoperative infection is likely. There is a high incidence of secondary

\*Chief Urological Service, Massachusetts General Hospital.

ture The operation results in incomplete removal of the gland and recurrent obstruction

Believing that these operative procedures were far from satisfactory, Millin studied, on cadavers, a new approach to the prostate He was convinced that since the prostate is essentially an extravesical organ, it should be removed by an extravesical approach As a result of his studies the retropubic operation was devised

*Preoperative preparation* The usual studies of renal and cardiovascular function are made before operation Intravenous pyelograms are obtained The patient is not catheterized unless there is urinary infection that fails to respond to treatment or unless renal function is poor Urethral-catheter drainage is avoided if possible

*Anesthesia* Low spinal anesthesia or Pentothal Sodium and nitrous oxide and oxygen are used The patient is cystoscoped for the first time on the operating table

*Operative technic* The bladder is exposed by a midline suprapubic incision The prevesical space is opened and cleared of fat A specially devised self-retaining retractor separates the rectus muscles and presses the bladder upward The veins on the anterior and lateral aspects of the prostate are exposed and carefully studied, since their distribution varies considerably These veins are situated in the prevesical layer of the pelvic fascia A large central vein arises from the deep dorsal vein of the penis, other veins lie on each side These veins are tied with the aid of a boomerang needle The prostatic capsule is opened transversely, and bleeding points are grasped between toothed forceps The incision is then carried down to the adenoma The apex of the prostatic mass is freed from the capsule, and the dissection is continued up to the bladder neck Here the prostate is freed by sharp dissection Bleeding points are controlled by ligature or electrocoagulation After removal of the hypertrophied gland a No 18 catheter is passed through the urethra to the bladder The prostatic capsule is closed with interrupted sutures The abdominal wound is closed, a small drain being left in the prevesical space

In his first 20 cases Millin reported no mortality and few postoperative complications Since this first report Millin has performed over 400 retropubic prostatectomies, which he described at the July, 1947, meeting of the American Urological Association in Buffalo, New York The mortality was approximately 4 per cent Millin's enthusiasm for the procedure was unbounded In his book describing the operation, he states that the extravesical retropubic approach to the prostate enables one to deal with all pathologic conditions within that organ and its contained urethra<sup>3</sup>

Among the audience who listened to Millin's presentation, there were a few skeptics, consisting of some who had seen Millin operate and who had

performed retropubic prostatectomies themselves Their enthusiasm seemed to be less than Millin's, tempered no doubt by their own experiences The prevailing opinion, however, was one of considerable interest and an eagerness to go home and "try it out"

Since then little has appeared in our own literature concerning this new method of removing the prostate, although the few reports available have been favorable

The recent French literature includes a description of retropubic prostatectomy with the report of 70 operations<sup>4</sup> The mortality was low, 2 deaths, functional results were excellent, and the authors were enthusiastic about the operation

There are reasons to believe that retropubic prostatectomy will have a very thorough trial in this country I do not agree that Millin's criticisms of present methods of relieving prostatic obstruction are entirely justified, but I admit that there is some truth in his comments on these procedures Although the perfect method of removing the prostate may not have been devised, I am not prepared to hand the laurel to retropubic prostatectomy until the long-term results are clear The urologist should be able to perform all the well recognized operations for the relief of prostatic obstruction

### *Carcinoma of the Bladder*

The classification of epithelial tumors of the bladder has always been confusing, and no one classification of these neoplasms has been generally accepted The Tumor Registry of the American Urological Association, after a study of over 1200 sections of these tumors in 1936, decided that it was not practical to segregate bladder neoplasms into definite groups corresponding to their cell types Jewett and Blackman,<sup>5</sup> after a histologic study of 97 cases of bladder tumor in which autopsy was performed, concluded that accurate classification of large infiltrating carcinomas of the bladder on the basis of cellular differentiation alone was impossible Many classifications of these tumors in the past have been confusing because they were too complicated

The present tendency is toward a simpler classification In 1939 Ash<sup>6</sup> stated that morphologically the tumors fall into two groups, papillary and sessile For the past seven years epithelial tumors of the bladder at the Massachusetts General Hospital have been classified as papillary and nonpapillary Tumors in each of these groups are graded I, II or III according to their microscopical appearance<sup>7</sup> Either the papillary tumors or the nonpapillary (sessile) tumors may infiltrate This simple classification is essentially the same as that used by the Bladder Tumor Registry, as outlined by Dart<sup>8</sup> and Ash<sup>9</sup> It has the advantage of correlating the gross or cystoscopic appearance of these tumors with their histologic characteristics Most bladder tumors

can be fairly accurately grouped and graded in this classification by cystoscopic examination alone.

It will be noticed that the term papilloma is omitted from this classification. Although these tumors do not have the histologic characteristics of malignancy, they are considered papillary carcinoma (Grade I). This is because their subsequent behavior is unpredictable. Ash<sup>8</sup> also avoids the term papilloma, since he regards it as impossible to determine by histologic examination how such tumors would behave clinically. Further basis for this point of view has recently been obtained from the work of Hovenan and Deming,<sup>10</sup> who report the successful heterologous transplantation of papillary tumors of the bladder in man to the anterior chamber of the eye of the guinea pig. One of their cases was that of a recurring papilloma of the bladder that had no evidence of malignancy. This tumor grew, however, in its transplanted site and thus established its identity as a true cancer.

A study of 107 post-mortem cases of bladder cancer was made by Jewett and Strong<sup>11</sup> to determine the relation of depth of penetration of the bladder wall to the incidence of metastases, lymphatic invasion and perivesical infiltration. The tumors were put into three groups: tumor cells confined to the submucosa, tumor infiltration extended into but not through the muscularis, and tumor cells extended through the muscular coat.

The curability in the first group is 100 per cent, that in the second group 86.6 per cent, and that in the third group 26 per cent. In other words, the incidence of local extravascular extension and metastases increases with the degree of penetration of the bladder wall. The most frequent sites of metastases are the regional lymph nodes, liver, lungs and bones, particularly the vertebrae and bony pelvis.<sup>12</sup>

The treatment of bladder cancer is changing, with more tendency toward radical surgery (total cystectomy). Complete removal of the bladder necessitates considerable serious surgery. The ureters must be transplanted to the skin or the large bowel. Skin ureterostomy is the safer procedure, but has obvious disadvantages. Evidence is accumulating that ureterointestinal anastomosis may be compatible with comfort and relative security. This has been adequately proved for nonmalignant diseases of the bladder such as exstrophy, but less so for cancer. Improved surgical technique, adequate preparation of the large bowel and the antibiotics have made ureterointestinal anastomosis a safer procedure than heretofore, with a mortality rate of probably from 10 to 20 per cent.<sup>13</sup> Higgins<sup>14</sup> recently reported no mortality from this operation in his last 22 cases.

The various methods employed in the treatment of bladder tumors are transurethral removal with or without radium, suprapubic operation with local

destruction of the tumor or partial cystectomy, total cystectomy and external radiation. Priestley<sup>15</sup> discusses the application of these different procedures to vesical neoplasm and describes the indications for each. Small, noninfiltrating lesions of low malignancy are best suited to transurethral treatment. Segmental resection of the bladder is employed for tumors that are well removed from the ureteral orifices, situated high in the bladder on the dome or lateral walls and of reasonable size. This method is generally used for infiltrating growths. The indications for total cystectomy are extensive low-grade lesions that involve most of the bladder or are present in many areas and frequently recur, highly malignant infiltrating tumors not removable by other measures and any neoplasm that cannot be removed completely without seriously affecting vesical function. External radiation is employed only in cases that are not suitable for surgery.

It is impossible at present to know how effective total cystectomy, as performed today, is as a cure for cancer of the bladder. In the past this operation has been done without the aid of modern methods of technique, preoperative preparation and the recent measures for controlling infection. Many patients whose tumors were so extensive that there was no reasonable hope of cure were formerly operated upon. As a result, the mortality was high, and complications were severe. Although total cystectomy involves a program of serious surgery, this procedure is becoming more simplified and standardized. It will doubtless be applied to more suitable cases and will eventually have a reasonable mortality.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

### Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C CABOT

TRACY B MALLORY, M D, *Editor*

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

#### CASE 34091

##### PRESENTATION OF CASE

A sixty-three-year-old Italian-born garage worker entered the hospital for the first time because of weakness of eight months' duration.

About eight months before admission he had a single episode of finding blood on his pillow and in his mouth on awakening. There were no previous or subsequent hemoptyses or hematemeses, but a productive cough developed shortly after this episode and progressed in severity up to admission. About 2 glassfuls of greenish sputum were produced daily. He had no pain but developed moderate exertional dyspnea, weakness and fatigability that necessitated giving up his job shortly after the onset of the present illness. Anorexia contributed to a 45-pound weight loss, and in the last month he developed night sweats and ankle edema.

The past history revealed an episode of epigastric pain twenty-three years before entry diagnosed as "stomach ulcer" and successfully relieved by an ulcer diet, which was followed for only six months. Active duodenal ulcer was allegedly demonstrated by x-ray examination one month before the onset of the present illness.

Physical examination revealed a pale man showing evidence of recent weight loss. There was slight clubbing of the fingers and toes. Lymphadenopathy was generalized with pea-sized to cherry-sized, movable, nontender rubbery nodes in the cervical, supraclavicular, inguinal, axillary and left epitrochlear regions. The right side of the chest was splinted, appeared smaller than the left and was flat to percussion below the level of the fifth rib posteriorly and in the axillary line. Tactile fremitus and spoken voice sounds were increased over the right apex and absent over the right middle and lower lobes. Examination of the heart was not remarkable except for its apparent shift to the right. The liver edge was smooth and nontender and extended 3 cm below the costal margin. There was a 3-cm reducible left direct inguinal hernia.

The temperature was 99°F, the pulse 76, and the respirations 28. The blood pressure was 115 systolic, 70 diastolic.

Examination of the blood disclosed a red-cell count of 3,700,000 and a white-cell count of 10,400 with 72 per cent neutrophils, 22 per cent lymphocytes and 6 per cent monocytes. The urine was normal. Guaiac tests on the stools were negative. The serum protein was 6.7 gm per 100 cc, with an albumin-globulin ratio of 0.76, the nonprotein nitrogen was 25 mg per 100 cc.

X-ray examination of the chest showed an area of increased density, with a fluid level in the apical division of the right lower lobe, the mediastinum was shifted to the right, and the left lung showed compensatory emphysema. There was some fluid in the right costophrenic sinus. Smears of sputum for acid-fast bacilli were negative. Cytologic smear of the sputum showed tumor cells, and a bronchoscopy revealed an irregular stenotic area in the right upper-lobe bronchus.

The right axillary lymph node was biopsied.

##### DIFFERENTIAL DIAGNOSIS

DR ALFRED KRANES: On first reading this seems like a fairly straightforward problem involving the differential diagnosis of bronchial stenosis with pulmonary atelectasis and infection. So far as the duodenal ulcer goes, I do not see how that can influence the discussion except so far as it might raise the question of whether the original episode of bleeding was hematemesis rather than a hemoptysis. When blood appears in the mouth as described here, it seems much more likely to come from the lung, but I see no way of settling that problem one way or the other.

At this point I think it might be wise to see the x-ray films.

DR STANLEY M WYMAN: Examination of the chest is not complete because we do not have an overexposed film to enable us to study the bronchi. The right base is denser than the left. The heart is deflected toward the right with the mediastinum and the trachea. There is an area of hazy homogeneous density occupying the lower middle third of the right lung field, and the right leaf of the diaphragm is obscured, probably by fluid. A definite cavity containing gas or fluid is seen close to the heart in the anteroposterior film and lying as described in the dorsal division of the right lower lobe. The right lower lobe appears decreased in size and appears to be airless. There is some compensatory emphysema in the right upper and probably right middle lobe. However, the patient had emphysema for many years, as seen by the increase in the anteroposterior diameter of the chest. There is probably some fine fibrosis through the left lung, which is otherwise clear. A film of the gastrointestinal tract shows the old deformed duodenum, which is consistent with a history of ulcer.

DR KRANE: Do you find any evidence of enlarged mediastinal lymph nodes?

DR WYMAN: I cannot be sure of any. The prominence in the region of the left hilus seems to be vascular, and no definite mediastinal lymph nodes are seen.

DR KRANE: No particular problem seems to be involved in this case until we come to the last sentence, about which a certain air of finality implies that the answer is to be found in the lymph-node biopsy. If that is so, it becomes more of a problem than was at first apparent, and it excludes immediately the one most common lesion that produces this clinical picture—namely, carcinoma of the bronchus. So far as I am aware, it is most unusual for carcinoma of the bronchus to metastasize generally to the lymph nodes without a good deal more evidence of metastases elsewhere. As a matter of fact, unless this was an extremely bizarre form of carcinomatous metastasis, I do not recall having seen simultaneous metastases to the inguinal, axillary, cervical and epitrochlear nodes. If the biopsy does give the answer, it excludes the possibility of carcinoma of the bronchus.

We come therefore to discussion of the more common types of lesions that produce simultaneous involvement of the lymph nodes and pulmonary parenchyma. There are not very many but the first that comes to mind is tuberculosis. Tuberculosis does cause cavitation and can cause bronchial obstruction due to inflammatory stricture, but I think there is little else in this picture on which to base a diagnosis of tuberculosis. The x-ray pictures are certainly far from typical. The negative sputum examinations are very much against it, and at this man's age (sixty-three) generalized glandular tuberculosis of the lymph nodes would be unusual. It is much more commonly a disease of younger persons. Even if the lymph node were tuberculous, I do not see why one need assume that the pulmonary lesion was. The diagnosis of the pulmonary lesion would have to rest on the finding of tubercle bacilli, but apparently they were not demonstrated.

Sarcoidosis is another possibility, but so far as I know, it does not produce bronchial obstruction or pulmonary cavitation. This is certainly not my idea of the x-ray picture of sarcoidosis. Would you entertain the possibility of sarcoid from these films, Dr Wyman?

DR WYMAN: No.

DR KRANE: A much more arresting possibility is lymphoma. Pulmonary cavitation and hemoptysis may occur in lymphoma and may be caused in one of several ways. The lymphoma may infiltrate the pulmonary parenchyma, central necrosis, cavitation and hemoptysis eventually resulting, or a mass of glands may cause extrinsic pressure on the bronchus, causing collapse and infection distal to the obstruction. Another possibility, of course, is

an endobronchial lymphoma, which is exceedingly rare.

Against lymphoma is the fact that there was no evidence of enlarged lymph nodes in the mediastinum to cause pressure on the bronchus, and furthermore, as I have already stated, intrinsic bronchial lesions have been described but are exceedingly rare. Another objection to lymphoma, although I cannot be sure of how valid it is, is the statement that tumor cells were found by the Vincent Laboratory in the cytologic examination of the sputum. I am doubtful whether lymphoma—that is, individual cells of lymphoma—can be identified as tumor cells by the Vincent Laboratory. I asked Dr Benjamin Castleman whether it would be possible to identify individual cells in a lymphoma as tumor cells. He said that he thought it might be possible if the tumor was exceedingly undifferentiated, such as a stem-cell lymphoma. Be that as it may, until I have seen it demonstrated I shall remain doubtful. A finding of tumor cells by the Vincent Laboratory still means carcinoma. The only way of making a diagnosis of lymphoma in this case—so far as the pulmonary lesion goes—is its response to x-ray therapy. If, following x-ray therapy, this lesion should completely disappear—with a dosage of about 1200 r—one would have to assume that it was lymphoma. However, should the lesion not disappear, it still might be lymphoma, because although x-ray treatment may be expected to cause regression of lymphomatous tissue or nodes, it could not be expected to reduce the secondary effects of the process such as infection. For the reasons that I have stated I doubt very much that the patient had lymphoma—at least in the lung.

If we disregard the lymph node, and I am afraid that I have to, we are on more familiar ground. The usual causes of this sort of picture in a person of this age are benign pulmonary abscess, which seems unlikely in view of the history and x-ray findings, and benign adenoma of the bronchus, which is consistent with everything described. Against the latter, however, is the patient's age, it occurs usually in the younger age group. Also against it is the fact that tumor cells were found in the sputum. A positive finding of tumor cells has usually been very significant and means carcinoma. Because of that fact and since the rest of the picture is so consistent with the diagnosis, I shall disregard the lymph nodes for the time being, and guess that the patient had a bronchiogenic carcinoma.

A PHYSICIAN: What was the result of the serologic test?

DR TRACY B. MALLORY: I think we can safely assume that it was negative.

A PHYSICIAN: Is it possible for a malignant tumor of the liver with metastases to the lung to invade the bronchus and give this picture?

DR KRANE: I think it is unlikely. Metastatic lesions to the lungs do not usually involve the

bronchi, but rather the lung parenchyma. Is that true, Dr Mallory?

DR MALLORY Yes

#### CLINICAL DIAGNOSES

Malignant lymphoma, lymphocytic type  
Squamous-cell carcinoma of lung

#### DR KRANES'S DIAGNOSIS

Bronchiogenic carcinoma

#### ANATOMICAL DIAGNOSES

*Epidermoid carcinoma (Grade II), of bronchus*  
*Malignant lymphoma, giant follicular type, of lymph nodes*

#### PATHOLOGICAL DISCUSSION

DR MALLORY We had two biopsies from this patient, one from the bronchus and one from a lymph node. They showed two entirely different types of tumor, the one from the bronchus was a squamous-cell carcinoma (Grade II), and the lymph node showed a giant follicular lymphoma. This has posed a great problem regarding treatment. It was believed that x-ray treatment of the lungs was more likely to do harm than good. Hence the tentative plan is to treat the patient with nitrogen mustard, which might influence both neoplasms.

### CASE 34092

#### PRESENTATION OF CASE

A twenty-seven-year-old dentist was admitted to the hospital because of persistent vomiting of twenty-four hours' duration.

The patient was said to have been in good health until one year before admission. He had served in the Navy for three years following graduation from dental school. His entire service had been in the United States. For about one year he had been thought to have a peptic ulcer and had occasional episodes of nausea and vomiting during that time. Five days before admission these episodes became more severe, and he was unable to go to his office. Twenty-four hours prior to admission persistent vomiting started, he became restless and was unable to sleep. When seen the morning of admission the patient was disoriented and obviously critically ill. Immediate hospitalization was advised.

The past history was noncontributory. One sibling had had pulmonary tuberculosis. There was no other history of familial disease.

Physical examination disclosed a hyperactive and disoriented patient. The skin was dry and diffusely tanned. There was no increased pigment in the folds of the skin. The lips and the nailbeds were dusky purple. There were multiple areas of pigment on the tongue about the color of egg plant. No pigment was seen on the buccal mucosa. There was a marked tremor of the tongue and extremities.

Motor activity was so great that special attendants were required to restrain the patient.

The temperature was 104°F, the pulse 134 and regular, and the respirations 24. The blood pressure was 50 systolic, 30 diastolic.

Examination of the blood revealed a hemoglobin of 13.2 gm, a hematocrit of 39 per cent and a white-cell count of 10,700, with 52 per cent neutrophils, 5 per cent young neutrophils, 4 per cent late myelocytes, 23 per cent lymphocytes, 13 per cent monocytes, 2 per cent eosinophils and 1 per cent basophils. The blood Hinton test was negative. Urinalysis revealed a specific gravity of 1.010, a ++ test for albumin, a rare hyaline cast, frequent coarse granular casts, a rare red cell and 1 white cell per high-power field. The nonprotein nitrogen of the blood serum was 100 mg and the sugar 67 mg per 100 cc, the sodium 135.7 milliequiv, the potassium 6.8 milliequiv and the carbon dioxide 17.4 milliequiv per liter.

A lumbar puncture done on the second hospital day revealed an initial pressure equivalent to 200 mm of water, with the patient poorly relaxed. A Pandy test was negative. The spinal-fluid protein was 30 mg per 100 cc and the gold-sol curve was 0001111100. The cell count gave 6 red cells and 3 lymphocytes per cubic millimeter. The Widal and Weil-Felix tests were negative. An x-ray film of the chest taken with a portable machine showed no abnormality. An electrocardiogram disclosed auricular tachycardia at a rate of 160 but no other abnormality.

In the first twenty-four hours the patient received 3000 cc of 5 per cent dextrose in physiologic saline solution, 500 cc of whole blood, 900 cc of physiologic saline solution and 3 ampules of sodium racemic lactate intravenously. In addition he received 150 cc of Upjohn's cortical extract intravenously, 10 mg of desoxycorticosterone intramuscularly and 40,000 units of penicillin every three hours. During the next twenty-four hours he received 4500 cc of 5 per cent dextrose in physiologic saline solution, 550 units of plasma, 3 ampules of sodium lactate, 60 cc of Upjohn's cortical extract and 10 mg of desoxycorticosterone. The penicillin was continued. On the third day he received 3000 cc of 5 per cent dextrose in physiologic saline solution, 2 ampules of sodium lactate, 500 cc of whole blood, 60 cc of Upjohn's cortical extract and 10 mg of desoxycorticosterone.

The temperature ranged from 103 to 105°F. The pulse was never recorded below 130. The blood pressure rose to 129 systolic, 45 diastolic, on the second day after the plasma. On the evening of the third day after being maintained above 100 all day it fell in the late evening to about 80 systolic, 44 diastolic. Clinically he changed little. He remained irrational and hyperactive. On the third day he developed a bronze blush over the arms and upper trunk with the appearance of small vesicles containing honey-colored fluid. Late on

the third day the pulse rose to 190, and the blood pressure became unobtainable. Examination of the blood on the third day showed the sugar to be 139 mg and the nonprotein nitrogen 46 mg per 100 cc., the sodium 152.0, the carbon dioxide 24.0 and the chloride 116.0 milliequiv per liter. The patient died early on the morning of the fourth day.

#### DIFFERENTIAL DIAGNOSIS

DR MARIAN ROPES Since no definite statement is made, I shall assume that the lung and neurologic examinations were essentially negative.

DR DANIEL ELLIS That is right.

DR ROPES At the outset I can think of no condition that satisfactorily explains all aspects of the picture. It is my impression that the disease was of at least one year's duration and was not merely an acute episode. There are various groups of symptoms to consider. There are five major ones: the gastrointestinal symptoms, the pigmentation, the evidence of renal failure, the suggestion of adrenal insufficiency and the central-nervous-system symptoms. We are told very little about the gastrointestinal symptoms. The patient had nausea and vomiting, however, and it was thought that he had a peptic ulcer.

There are various conditions that one must think of with the combination of gastrointestinal symptoms and pigmentation. Porphyrria is one that comes to mind. However, there is relatively little else in the picture to support that diagnosis. The type of pigmentation is perhaps consistent with it, and the gastrointestinal symptoms surely are consistent. The absence of paralysis and the presence of as much irritation from the point of view of the nervous system are not consistent, and there is nothing else to support the diagnosis. He surely did not have the type in which a colored porphyrin is present in the urine.

One thinks of hemochromatosis, but in the absence of diabetes and liver enlargement and in the presence of definite renal involvement and marked central-nervous-system symptoms, this can be discarded relatively easily. Also, with the pigmentation and chronic involvement I wondered about the possibility of some type of poisoning. The diffuse pigmentation described was surely not that of argyria, and argyria would not explain the rest of the picture. Methemoglobinemia is suggested by the color of the lips and the nailbeds. Again, that would not explain the rest of the picture. There is no further evidence of this, nor is there evidence of any other type of poisoning.

One condition suggested by the gastrointestinal symptoms and pigmentation that must be considered is Addison's disease, with which nausea and vomiting over the course of a year would certainly be possible. However, it would be very unusual not to have had other symptoms — at least weakness during the same period. The pigmentation is in general consistent, the tongue and the skin are charac-

but with such marked pigmentation as I gather he had I would expect some in the folds of the skin. The pigmentation might be a racial characteristic, although we are not told what his race was and this would not explain the pigmentation on the tongue. Certainly, the final crisis could be consistent with that of adrenal insufficiency. Again, the degree of urinary changes was greater than that usually found during an adrenal crisis. Though uremia may occur I would be surprised to find as large a number of casts present during the crisis. Similarly, the central-nervous system reaction is greater than that usually seen in a crisis. However, in the presence of uremia this is relatively easily ascribed to uremia and not to any underlying adrenal failure. The fever again is much higher than one would expect and surely suggests the presence of infection. That brings up the question of the cause of the adrenal failure if present in this patient. There was a history of tuberculosis in the family. Tuberculosis is not the most common cause of adrenal failure, hypoplasia of the adrenal glands being a more common cause of Addison's disease. Similarly, the infection suggested by the fever and the cellular reaction in the blood raise the question of adrenal insufficiency secondary to an acute infection. Some of the laboratory tests are consistent with Addison's disease. The hypoglycemia is typical. The potassium is elevated, but the normal or low sodium is unusual with this degree of potassium elevation. In fact it is also interesting that a patient with elevation of potassium had a normal electrocardiogram except for the tachycardia.

For the moment, therefore, to leave adrenal insufficiency and consider one of the other possible explanations of the entire picture, I would swing to renal failure. There is no question that this patient had renal failure at the time of admission — whether primary or secondary is more of a question. The nausea and vomiting could easily have been due to a slow onset of renal insufficiency. It was present for a somewhat longer period than one commonly sees, but it was inside the limits of what is seen. There is no way with this diagnosis to explain the pigmentation. In my opinion it cannot all be related to the renal failure unless he had porphyria for which I find no other evidence. The degree of fever is not that seen in renal failure. The potassium elevation could have been due to the severe renal failure or to the associated shock, with passage of potassium out through the cells, so that in itself does not need to make one insist on the presence of adrenal insufficiency.

When one considers the possible causes of renal disease in this patient one notices first the relatively minimal urinary changes, the albuminuria with frequent granular casts. There were only rare red and white cells. This raises the question of some of the diseases in which such urinary findings are found commonly, such as myeloma and amyloidosis. I find nothing in the record to

myeloma. Similarly, I find nothing to suggest an underlying cause of amyloidosis. That does not rule out the possibility of amyloid disease of the kidney, but without further support it need not be considered further. When one thinks of periarteritis nodosa or other vascular change as a cause of the nephritis, there is again very little evidence in the rest of the picture for such a diagnosis. So, in terms of renal failure one should think of more common causes at this age, and with no evidence of history of urinary infection the possibility of glomerulonephritis should be put as the most likely explanation of the renal disease. I think that even if adrenal disease was present this patient also had renal disease.

I think that one must consider the possibility of infection in this case. I doubt that any infection that can produce this picture could have been present for a year and explain the earlier symptoms. That could be contradicted if one said that tuberculosis in some form might have been present, but the symptoms throughout the year would be very unusual for tuberculosis in the gastrointestinal tract or abdomen. I can think of no other infection that could explain the symptoms during the year. The terminal event suggests infection, but whether an underlying disease was precipitated by a severe infection is the question. The final rash means very little to me. A bronze blush with vesicles containing honey-colored fluid is difficult to explain but perhaps is suggestive of infection or possibly a disease of unknown cause, such as erythema multiforme exudativum. The lesions described would fit that disease, but in the absence of mouth lesions, eye lesions or anything else consistent with the picture, erythema multiforme exudativum could not be supported. One would have to consider more seriously a meningococcal septicemia leading to adrenal failure. However, the duration of the disease (five days before admission and four days after) would be unusual. There was a five-day period without treatment during which the patient was ill but not so critically ill as patients with a combination of meningococcal septicemia and adrenal involvement. Again, the rash was surely not that ordinarily seen in meningococcal infection. I think the high fever, the cellular reaction in the blood and possibly the rash all suggest infection, but without any evidence of blood cultures or other studies it is impossible to say whether or not this patient had a septicemia. The rash with an apparently thin fluid in the vesicles, if related to infection, suggests a streptococcal infection.

Originally, I had thought of the possibility of a tumor involving the region of the kidney or adrenal gland but was unable to think of any condition that would involve so completely either both kidneys or both adrenal glands, so I have discarded that possibility.

In an attempt to summarize, I shall say that it is difficult to determine whether or not both adrenal and renal failure were present in this patient, but my choice, with the knowledge given here, is that there was an underlying renal disease and that the terminal uremia was precipitated by a superimposed infection. I find nothing to indicate the nature of the superimposed infection.

DR BERNARD JACOBSON: Was the rash caused by the penicillin?

DR ELLIS: That is what we wondered about when we first saw it. It became most apparent about 6:00 o'clock during the night before the patient died. We did not think it was any more than that which one sees in patients who have had a high fever for a long time.

DR ROPES: Can you explain the localization? You described it on the trunk and arms rather than generalized.

DR ELLIS: There is no explanation for that at all. But the striking feature about this patient when first seen was the cyanosis of the nails, duskeness of the lips, dry skin and hypotension. By the time he got to the hospital his motor activity was the thing that was very prominent and persisted until about 6:00 o'clock the night before he died. The urinary findings, the high nonprotein nitrogen and the relatively low specific gravity, in the face of the very marked dehydration, bothered us, as they did Dr Ropes. For the first twelve hours we thought that he had anuria, but when he was catheterized at the end of that time we obtained a large volume of urine, with a specific gravity of 1.010 to 1.012 and from that time on he voided quite freely and was incontinent. We were also bothered during the course of the illness by the persistently high fever and the persistent tachycardia. We believed as Dr Ropes did that the possibilities were adrenal insufficiency, renal insufficiency and infection. We were left with no other choice except to treat him as if he had adrenal insufficiency, and to treat infection, if he had one, with penicillin and try to get him back to a normal electrolyte balance. The treatment was given in detail in this abstract with the hope that we would have some discussion about it after the diagnosis was made. We believed at the time that the patient died that the clinical diagnosis was adrenal insufficiency. We were unable to get any proof that he had an infection although we tried hard and suspected that he might have meningococcal septicemia. Blood cultures were taken, and the last time I saw the record they were not recorded.

DR TRACY B. MALLORY: They remained negative.

#### CLINICAL DIAGNOSES

Acute adrenal insufficiency

Acute infection and septicemia (cause undetermined)

## DR ROPES'S DIAGNOSES

Renal disease (? glomerulonephritis)  
Terminal uremia  
Septicemia?

## ANATOMICAL DIAGNOSES

Primary atrophy of adrenal cortex  
Addison's disease  
Chronic thyroiditis, moderate  
Chronic hepatitis, nonspecific  
Persistent thymus

## PATHOLOGICAL DISCUSSION

DR MALLORY I do not know that we can explain the whole picture. The outstanding feature of the autopsy was atrophy of the adrenal glands. They were estimated to weigh between 2 and 3 gm., with little cortical tissue, what remained appeared to be chiefly medulla.

On microscopical examination we found scattered fragments of persistent cortex. The cells were very unusual in type. They were four or five times as large as normal and contained practically no lipid. A few did contain the normal pigment seen in the reticular layer. The cells were clumped in small nodules, with no orderly cord formation. Some clusters of lymphocytes were present.

There were no other significant gross findings at autopsy. The pituitary and thyroid glands, testes and parathyroid glands were grossly normal. The thymus was quite large, weighed 30 gm. and was evidently active, with very little involution. There was a terminal congestion and edema of the lung but no evidence of pneumonia. On microscopical examination the pituitary gland appeared normal, the thyroid gland showed moderately severe thyroiditis, with some degree of atrophy, the parathyroid glands were normal, and the testes showed a slight depression of activity. The early stages of spermatogenesis were present but mature spermatozoa were infrequent. But any patient near death can show that much depression of spermatogenesis.

One surprising microscopical finding was a considerable degree of lymphocytic infiltration of all the portal areas of the liver, but I do not know what to make of that. It did not look like infectious hepatitis. I have to leave it without explanation. It is beyond the normal limits.

DR ALFRED KRAVES Were the kidneys normal?

DR MALLORY Entirely — grossly and microscopically.

DR FULLER ALBRIGHT When I saw this man the problem was one of treatment. It had already been decided that he had Addison's disease. We did not know the cause of the Addison's disease. What about therapy? The question is whether we over-treat or undertreat these cases. I think that the

tendency is to overtreat them. The trouble is that there is no easy laboratory test that one can perform quickly and that parallels the patient's condition. Dr Robert Loeb,<sup>1</sup> of New York, has shown that a patient can die with a high fever and still have normal serum electrolytes. Some unknown factor is present that we do not know how to evaluate. I think, if anything, we overtreated this patient, the serum sodium was high — 150 milliequivalents per liter (the normal is equal to 140 milliequivalents per liter).

A word about the term "atrophy" — we divide cases of Addison's disease into two pathological groups: tuberculosis and something else, which is usually called atrophy. Is that right, Dr Mallory?

DR MALLORY Yes.

DR ALBRIGHT Does this agree entirely with other cases that you call atrophy?

DR MALLORY That is a difficult decision so far as I am concerned.

DR ALBRIGHT When I was in Vienna, Erdheim showed a case with this second kind of lesion. One adrenal gland was entirely gone, and half the other. He said that eventually the patient would have had Addison's disease when the second gland had become completely involved. This disease is very different from the atrophy that occurs when there is no pituitary stimulus to the adrenal cortex. That is real atrophy. This is something else. The cells disappear by some sort of necrosis, and the whole gland is not involved simultaneously. It is not my idea of atrophy. It is more analogous to thyroiditis.

DR MALLORY The problem that Dr Albright raises is essentially semantic, and I cannot solve it for him. "Atrophy" and "involution" both etymologically connote a comparatively slow shrinkage of tissue such as occurs with aging or with disease. Yet "atrophy" has been in accepted medical usage for over a century to describe fulminant necrosis of the liver. Friedman<sup>2</sup> in reporting a group of 26 cases of Addison's disease recently used the term "contraction," borrowed from the terminology of renal disease. I cannot see that it is an improvement. I do agree with Dr Albright that in this case there was active destruction of the adrenal cortex rather than the secondary atrophy seen in Simmonds's disease.

DR JACOBSON In these cases of cortical necrosis of the kidney in women, what is the adrenal picture?

DR MALLORY It may be normal. We have also seen cases in which the adrenal gland shows the same type of necrosis as the kidney, and hemorrhagic necrosis has been reported in the pituitary gland also.

## FEBRUARY MEETING OF THE COUNCIL

A STATED meeting of the Council of the Massachusetts Medical Society was held on February 4, 1948. Among the business, which was transacted with more than usual dispatch, the following items are of particular interest or importance.

The President, under the new arrangement between the Society and the Boston Medical Library, nominated the following to serve as trustees of the Library representing the Society: Dr. Curtis C. Tripp, of New Bedford, Dr. John J. Curley, of Leominster, Dr. Edward S. O'Keefe, of Lynn, and Dr. Albert Ehrenfried, of Brookline.

During consideration of the report of the Committee on Public Relations, discussion took place as to whether the Council should endorse the objectives of the National Physicians Committee, and a motion was offered to this effect. In view of the

fact that the Committee on Public Relations had appointed a subcommittee to meet with the Committee on Medical Economics and bring in a report on this matter to the Council, the motion was tabled.

Dr. John F. Conlin presented a general summary of his work as Director of Medical Information and Education, stressing the importance of public relations to individual physicians as well as to society at large. With reference to the woman's auxiliaries he reported that Norfolk and Suffolk are organized, with Essex South and Middlesex South well on the way. In April the districts that are organized will form a nucleus for the state auxiliary.

The report of the Committee on Cancer, asking for approval of the establishment of a cancer-detection clinic at the Palmer Memorial Hospital, was accepted, and the establishment of this clinic approved in principle. A similar request had been tabled at the October meeting of the Council. In this more comprehensive report it was explained that such a clinic would serve as a proving ground for different types of diagnostic methods and as a center where physicians might come to determine procedures applicable to the problems of their own practice.

The report of the Committee of Seven that had been appointed at the October meeting "to study the need for a full-time secretary and to define the duties of the Secretary, Director of Medical Information and Education, and the Executive Secretary of the Society" was accepted. This report recommended the employment of a full-time secretary and called for certain revisions in the by-laws of the Society that would implement the proposed changes.

Under suspension of rules, House Bill 104 introduced in the state legislature was approved. This bill designates the Massachusetts Department of Public Health as the agent, under the Federal Hospital Survey and Construction Act, to survey the hospital needs of the Commonwealth. Also under suspension of rules the Council adopted a resolution offered by Dr. Vlado A. Getting approving the turning over to the American Red Cross of the blood and blood-derivative program of the Commonwealth. The Red Cross voted in June, 1947, to assume this program, which has been conducted by

the Department of Public Health, on condition that the Massachusetts Medical Society approve in principle and serve, with the Department, in an advisory capacity

### THE RED CROSS NEEDS YOUR HELP

THE annual drive for the Greater Boston Red Cross Fund was launched at an opening rally held in Symphony Hall on February 25. The campaign will occupy the month of March. The Greater Boston share of the national goal of \$75,000,000 is \$1,440,000. These quotas have been increased from last year's goals of \$60,000,000 and \$1,280,000 respectively.

The increased sums of money sought reflect only the increased costs of human activities in general. The public is reminded that this year greater sums are needed for an equal job, despite greater emphasis on a peacetime program, the Red Cross is continuing and even expanding its work for veterans and their dependents.

Recounting past services of the Red Cross may help to remind us that they will be needed again and that this great humanitarian organization requires the nation's unflinching support.

During the past fiscal year nearly 100,000 persons received emergency help and rehabilitation in 312 disaster operations, in the first ten months of 1947 alone, disaster relief appropriations approximated \$9,500,000. Financial assistance to servicemen and veterans and their families amounted to \$11,944,365 for the year. To turn from dollars to hours, volunteer special services workers gave 25,000,000 of the latter.

In 1947 the American Red Cross recruited 2564 nurses to aid in the campaign against poliomyelitis. Red Cross public-health nurses made 351,600 visits, and 118,340 certificates for completion of home-nursing service courses were issued during the year. In retrospect it is a source of satisfaction to recall that 11,230,000 certificates of proficiency in first aid have been issued since that program was instituted in 1910, and that since the program to "waterproof" America was launched in 1914, the nation's drowning rate has been halved.

The Junior Red Cross of 19,270,811 members will ship a million boxes to children overseas during the current school year. 34 nations are participating in

the Junior Red Cross international school-correspondence program.

The national blood program, when completely organized, will make whole blood and its derivatives available without cost to all the people of our nation.

This is but a partial classification of the major activities of the Red Cross. To carry on with them and with its other commitments requires the continued support that has always so gladly been given.

### ROBERT NASON NYE MEMORIAL STUDY

THE Massachusetts Division of the American Cancer Society has voted a grant to the Massachusetts General Hospital of approximately \$2500 for a particular purpose. The sum thus appropriated represents the money so generously donated in memory of the late Dr. Robert N. Nye. The purpose is to initiate and at least partly support the Robert Nason Nye Memorial Study.

This study, a long-desired project of the X-ray Department of the Massachusetts General Hospital, where Dr. Nye served his internship, is concerned with the evaluation of changes in the peripheral blood correlated with known amounts of exposure to radiation sustained by the employees and staff of the X-ray Department. Among other matters to be studied is the incidence of leukemia among such workers.

The study will be under the supervision of Dr. Laurence L. Robbins, roentgenologist of the Hospital, with the assistance of Dr. Francis M. Hunter, of the Clinical Laboratory, and in consultation with Dr. John G. Trump, of the Massachusetts Institute of Technology.

### MASSACHUSETTS MEDICAL SOCIETY

#### BLUE CROSS ENROLLMENT

The following letter explains the present situation regarding enrollment in Blue Cross of members of the Massachusetts Medical Society. Blue Cross has already discontinued the practice of allowing enrollments on the first of each month and adopted the policy of permitting them only once a year at the time of a general reopening for all nonsubscribing members. August had been suggested as a convenient month for this reopening.

II QUIMBY GALLUPE  
Secretary

February 6, 1948

Mr Robert St. B. Boyd, Executive Secretary  
Massachusetts Medical Society  
8 Fenway  
Boston 15, Massachusetts  
Dear Mr Boyd

I regret to state now that it is impossible for me to tell you whether or not August may be the re-opening date for your group and it is difficult for me to say at this time whether or not there will be another opportunity for members of the Medical Society to join the Blue Cross Plan

Please understand that this is due only to a complete change in our methods of enrollment and every effort is going to be made to satisfy groups such as yours which were enrolled on Direct Payment. I have taken this matter up with Mr Cunningham and he has told me that your group will be discussed shortly as to whether re-openings will be allowed in such groups

Please be advised that as soon as possible I will let you know whether or not your group may be re-opened, if so, what month will be preferable and also the necessary number of applicants to be secured at that time

I am sorry that I am not in a position to give you complete information for presentation in your *Journal* as I know that was your desire but you will realize that we are in a very difficult position at this particular time due to the high incidence of hospitalization and the many changes now being made of necessity have left us with many unsolved problems

I will notify you just as soon as possible

JOHN H McLAUGHLIN  
Enrollment Representative

Massachusetts Hospital Service Inc  
Massachusetts Medical Service  
38 Chauncy Street  
Boston

## NEW HAMPSHIRE MEDICAL SOCIETY

### DEATHS

CHENEY — Harry A. Cheney, M.D., of Campton, died on July 15. He was in his seventy-seventh year.

Dr. Cheney received his degree from University of Vermont College of Medicine in 1894. He was a member of the staff of the Scoville Memorial Hospital in Plymouth.

HUCKINS — Thion H. Huckins, M.D., of Tilton, died on January 3. He was in his seventy-fifth year.

Dr. Huckins received his degree from Dartmouth Medical School in 1902. He was a member of the staff of Franklin Hospital.

His widow, a son and a brother survive.

SULLIVAN — Daniel J. Sullivan, M.D., of Manchester, died on December 16. He was in his fifty-sixth year.

Dr. Sullivan received his degree from Tufts College Medical School in 1916. He was formerly chief of the surgical staff of Sacred Heart Hospital and surgeon on the staff of Hillsborough County General Hospital. He was secretary of the New England Regional Committee of Fractures and was a fellow of the American Medical Association.

His widow, two sons, two daughters and a sister survive.

## A HUNDRED YEARS AGO

The Counsellors of the Mass Medical Society will meet at their rooms in the Masonic Temple, Tremont st., at 11 o'clock in the morning of February 2. Business matters of peculiar interest will be acted upon, and it is therefore desirable that gentlemen should be in their seats at the specified hour. — A melancholy interest is connected with the sudden and suicidal death of Dr. Horace Wells, from the circumstance of his

name being associated with the discovery of the inhalation of gases to overcome consciousness in surgical operations. He labored incessantly to establish his claim to the honor of discovery, and certainly produced a mass of testimony that convinced many that his researches, experiments, and suggestions influenced others to proceed in a course of investigation, that finally led to the triumphant discovery of the anaesthetic properties of sulphuric ether, and subsequently, under the clear-sighted exertions of Dr. Simpson, of Edinburgh, of the same surprising qualities in chloroform. — Messrs W. B. Little and Co., Hanover street, Boston, are manufacturing this new agent in large quantities. Much of it is packed up in phials small enough to be carried in a vest pocket, and secured at the cork in a manner to prevent loss by evaporation. Dr. C. T. Jackson, the chemist, whose reputation is as extensive as the boundaries of Science, speaks with entire confidence of the purity and excellence of Mr. Little's chloroform for all the purposes for which it may be required. The demand for it almost exceeds belief — and we are almost disposed to ask under what circumstances it can all be used. — A bill has been before the legislature of New York, which proposes a fine of \$25 for selling adulterated drugs and medicines, if known to be such, and the same fine where the ingredients of a compound are not stated on the label, in legible English, but it was finally lost by a decisive vote. — 140 students are in attendance on the Medical lectures in Harvard University, the present season. — At Bellevue Hospital, out of 600 patients there are said to be over 200 of Typhus Fever, while three of the Assistant Physicians are sick of the fever, and two others but just recovering from an attack. — Extracted from the *Boston Medical and Surgical Journal*, February, 1848.

R. F.

## MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

### THE COMMONWEALTH'S RHEUMATIC-FEVER PROGRAM

Several hundreds of children in Massachusetts are victims of rheumatic fever each year. Some of these children will be crippled or handicapped by this disease, others, without actual cardiac damage from a first attack, will need protection from further attacks. The second group is particularly important in the field of preventive medicine, and efforts should be directed toward provision of the most healthful living conditions possible. General health supervision and regular medical examinations will help to forestall the development of the more serious infections.

Another important part of a rheumatic-fever program is to make a definite diagnosis of the child

who has questionable heart disease and to interpret to the family just what degree of activity is possible. Unnecessary limitation of a child's life may be as detrimental to his future as too great physical effort. His possibilities as a self-supporting and useful citizen should be considered in any plan for care and aid to the child with rheumatic heart disease.

The Massachusetts Rheumatic Fever Program is offering in the Northeastern Health District diagnostic and consultative service, as well as complete clinic care, follow-up study and hospitalization when needed, for patients under twenty-one years of age. Further information and application blanks can be obtained from the District Health Office, 367 Main Street, Wakefield (Telephone, CRystal 9-1118).

## MISCELLANY

### NOTE

The following appointments to the teaching staff of Harvard Medical School were recently announced: Keith Merrill Jr., of Herndon, Virginia (A.B. Yale University 1940, M.D. Harvard University 1944), research fellow in surgery; Peter Howard Nash of Kent England (B.A. Cambridge 1938, M.A. Cambridge 1945, M.B.B.Chir. Cambridge 1941, D.P.H. London 1947), research fellow in medicine; John Robertson Sinton, of London England (M.B., B.Surg. London University 1944, M.R.C.P. Royal College of Physicians of London 1946), research fellow in medicine; Robert John Walsh, of New South Wales, Australia (M.B. University of Sydney 1939, B.S. University of Sydney 1939), research fellow in medicine; Daniel Sumner Ellis, of Cambridge (M.D. Harvard University 1939), assistant in medicine; William Burton Ayre, of Montreal, Canada (B.A. University of Alberta 1938, M.D. University of Alberta 1943), research fellow in medicine; Donald Harting of Cambridge (S.B. Harvard University 1945, M.D. Harvard University 1946), research fellow in pediatrics; Lytt Irvine Gardner of Cambridge (A.B. University of North Carolina 1938, M.A. University of North Carolina 1940, M.D. Harvard University 1945), research fellow in pediatrics; and John Martin Weller, of Oak Park, Illinois (A.B. University of Michigan 1940, M.D. Harvard University 1943), teaching fellow in biologic chemistry.

## NEW MEDICAL DIRECTOR UNITED STATES VETERANS ADMINISTRATION

Dr. Paul B. Magnuson, prominent orthopedic surgeon and closely identified with the reorganization of medical care in Veterans Administration hospitals, has been named chief medical director for the United States Veterans Administration.

Dr. Magnuson, former professor of surgery and chairman of the Department of Bone and Joint Surgery at Northwestern University Medical School, succeeds Dr. Paul R. Hawley who resigned on January 1 as medical chief and who now is serving as special assistant and adviser on medical problems.

## NEW YORK TUBERCULOSIS AND HEALTH ASSOCIATION

Dr. Kendall Emerson was elected president of the New York Tuberculosis and Health Association at the annual meeting held in the Association's headquarters, 386 Fourth Avenue, Manhattan, on January 27. All other officers were re-elected and two new members were elected to the Board of Directors.

The new Board members are Dr. Norman Plummer, medical director of the New York Telephone Company, and Dr. William Hunter Stearns, associate visiting physician, Chest

Service, Bellevue Hospital and instructor in medicine, College of Physicians and Surgeons, Columbia University.

Dr. Emerson, who was a charter member of the American College of Surgeons, was managing director of the National Tuberculosis Association for nineteen years until his retirement on December 31, 1947. He began his career as an orthopedic and general surgeon in Worcester, Massachusetts, and from 1923 to 1928 was chief of surgical services in the Worcester Memorial Hospital. In World War I he served with the British forces in the Royal Army Medical Corps from 1916 to 1918 and with the United States Army Medical Corps from 1918 to 1919. He was deputy commissioner and medical director for Europe for the American Red Cross during 1920-1921.

The annual health conference of the Association will be held in the Hotel Pennsylvania, New York City, on March 9.

## LASKER FOUNDATION AWARD

Dr. John Rock, of Boston, received on January 27, 1948, the Lasker Foundation Award and medal from the Planned Parenthood Federation of America. The award was made because of his investigations into the causes and cure of sterility.

## NATIONAL BLOOD PROGRAM

The American Red Cross has announced the appointment of Dr. Louis K. Diamond, assistant professor of pediatrics at Harvard Medical School, as technical director of the National Blood Program. Dr. Diamond is also director of the Boston Children's Hospital Blood Bank and Research Laboratory, director of the Blood Grouping Laboratory of Boston and consultant in pediatric hematology at the Massachusetts General Hospital.

The most recently opened donor center in the \$10,000,000 chain has been established at Stockton, California.

## EFFECT OF WAR ON CHILDREN

Award of a \$20,000 research grant to the International Committee on Mental Hygiene under the National Mental Health Act was recently announced.

The grant will be used under the direction of Dr. David Levy, professor of psychiatry, Columbia University College of Physicians and Surgeons, for a study of the effect of war on children. It will be presented at the International Congress on Mental Health, to be held in London in August.

## MENTAL HEALTH CLINIC

The first United States Public Health Service demonstration mental health clinic has been opened in Prince Georges County, Maryland. The clinic will be operated jointly by the Maryland State Department of Health and the Public Health Service, with federal funds under the National Mental Health Act. Forty thousand dollars has been appropriated for the fiscal year 1948.

The clinic is under the direction of Dr. Mabel Ross, child psychiatrist formerly with the Johns Hopkins Hospital. Psychiatric service is offered to all residents of Prince Georges County, which has a population of 140,000.

## CORRESPONDENCE

### OLD SPANISH SWINDLE IN NEW FORM

To the Editor: A communication from the acting Inspector in charge, Post Office Department, Boston, is transmitted herewith for publication in the *Journal* since the fraud described applies to physicians as well as to dentists and members of other professions. The letter is as follows:

The following information is respectfully offered as material for inclusion in a forthcoming issue of the *New England Journal of Medicine*.

Tennison Jefferson, post office Inspector in charge, Boston, estimates that over a thousand Spanish prisoner swindle letters have been mailed recently at Mexico City, Mexico, addressed to doctors, dentists and others through-

out New England. The operators of the revived swindle appear to be using names and addresses selected from publications such as *Who's Who in America* and those listing the names of doctors and dentists.

Jefferson, who has personally investigated most of the major foreign lotteries and frauds during the past decade, explained that these prisoner letters are allegedly mailed by a man imprisoned in Mexico for bankruptcy. The prisoner states in his letter that he needs only a few thousand dollars to lift an embargo on his trunk, containing \$375,000.00 in United States currency and held in a customhouse in the United States. One third of this money, or \$125,000.00, is offered to the addressee of the letter if he will come to Mexico with \$2,000.00 in cash to aid the prisoner. As evidence of good faith the prisoner also offers to place his "dear daughter" under the protection of the man to whom the letter is addressed.

He described the swindle as one of the oldest in existence, having originated in Spain many years ago. Its headquarters were moved to Mexico around 1900. Information furnished to the Post Office Inspection Service shows that many old family archives contain Spanish-prisoner letters received before the turn of the present century. Jefferson remarked, "Incredible as it may seem, during the years that this swindle has operated the number of Americans gullible enough to respond with cash to its promise of easy money has been sufficient to keep it alive. These swindlers are currently seeking a new crop of post war victims."

Inspector in Charge Jefferson requests those who receive Spanish prisoner letters to mail or bring them promptly to his office in the Federal Building, Boston, so that United States mail addressed to the swindlers may be identified therefrom and held under postal fraud orders.

## NOTICES

### ANNOUNCEMENT

Drs Edward L. Young, Walter E. Garrey, Walter E. Wilson, Jr., and Howard M. Trafton announce the removal of their offices to 1180 Beacon Street, Brookline.

### HARVARD MEDICAL SOCIETY

A meeting of the Harvard Medical Society will be held in the amphitheater of Building D, Harvard Medical School, on Tuesday, March 9. A symposium on virus diseases will be presented.

#### PROGRAM

##### Afternoon (4 30 to 6 30)

Max Bovarnick, M D. Chemical Nature of the Virus Receptors in Red Cells

John C. Snyder, M D. Chemotherapy of Rickettsial Diseases

Herbert R. Morgan, M D. Experiments on Chemotherapy with Agents of the Psittacosis Lymphogranuloma Group

Charles A. Janeway, M D. The Effect of M-casles on the Nephrotic Syndrome

##### Supper in Vanderbilt Hall at 6 30 p m

##### Evening (8 00 to 10 00)

John F. Enders, Ph D. Mumps

Maxwell Finland, M D. Influenza

F S Cheever, M D. Epidemic Diarrhea of Suckling Mice

Robert Rustigian, Ph D. Studies on Immunity of Theiler's Virus

Subsequent meetings will be held on April 13 and May 11

### NEW ENGLAND SOCIETY OF ANESTHESIOLOGISTS

A meeting of the New England Society of Anesthesiologists will be held in the Bigelow Amphitheater of the White Building, Massachusetts General Hospital, on Tuesday, March 9, at 8 p m. Dr. Ralph M. Tovell's group will present the following program:

The Physiologic Basis for Resuscitation of the Newborn  
Dr. David M. Little, Jr.

Cardiovascular Collapse During Subarachnoid Block  
Recovery following administration of procaine.  
Dr. Robert R. Cross

Treatment of Cardiovascular Emergencies during Anesthesia  
Case report.  
Dr. Harvey F. Dritz

Proved Ventricular Fibrillation during General Anesthesia with Complete Recovery.  
Dr. R. Starr Lampson

Physicians and medical students are also invited to attend a meeting of the Anesthesia Study Commission to be held at Boston University School of Medicine on Tuesday, March 30, at 8 p m. Three interesting cases are to be presented. Guest discussants will review the cases.

### AMERICAN HOSPITAL ASSOCIATION

The fiftieth-anniversary convention of the American Hospital Association will be held in Atlantic City, New Jersey, from September 20 to 23, with headquarters at the Traymore Hotel and with meetings and exhibits at the Atlantic City Convention Hall.

The program, which is devoted to the subject "Hospitals — Vital to Better Living," will consist of morning and afternoon sessions concerned with important issues and problems of the care of patients and of hospital finances, as well as the role of the hospital in community life and the challenge to hospitals. Special events will include the sessions of the House of Delegates, an informal reception followed by a buffet dinner and the annual banquet. Commercial and educational exhibits will be conducted.

### SOCIETY MEETINGS AND CONFERENCES

#### CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, MARCH 4

##### THURSDAY, MARCH 4

12 00 p m. Clinicopathological Conference. Nurses Home Allerton Hospital, Brookline.

##### FRIDAY, MARCH 5

\*10 00 a m.—12 00 m. Medical Staff Rounds. Peter Bent Brigham Hospital.

##### MONDAY, MARCH 8

12 00 m. Clinicopathological Conference. Margaret Jewett Hall, Mt. Auburn Hospital, Cambridge.

\*12 15—1 15 p m. Clinicopathological Conference. Peter Bent Brigham Hospital.

##### TUESDAY, MARCH 9

\*12 15—1 15 p m. Clinicoroentgenological Conference. Peter Bent Brigham Hospital.

\*1 30—2 30 p m. Pediatric Rounds. Burnham Memorial Hospital for Children, Massachusetts General Hospital.

4 30 p m. Harvard Medical Society. Amphitheater of Building D, Harvard Medical School.

8 00 p m. New England Society of Anesthesiologists. Bigelow Amphitheater of the White Building, Massachusetts General Hospital.

##### WEDNESDAY, MARCH 10

\*12 00 m. Grand Rounds and Clinicopathological Conference (Children's Hospital). Amphitheater. Peter Bent Brigham Hospital.

\*2 00—3 00 p m. Combined Clinic by the Medical Surgical and Orthopedic Services. Amphitheater. Children's Hospital.

\*Open to the medical profession.

# BACKGROUND

The use of cow's milk, water and carbohydrate mixtures represents the one system of

infant feeding that consistently, for over three decades, has received universal pediatric

recognition. No carbohydrate employed in this system of infant feeding enjoys so rich and enduring a background of authoritative clinical experience as Dextri Maltose.

## THE OCCURRENCE OF EXTENSOR SPASM IN PATIENTS WITH COMPLETE TRANSECTION OF THE SPINAL CORD\*

MARTIN B. MACHT, PH.D., M.D.,† AND ROBERT A. KUHN, M.D.‡

FRAMINGHAM, MASSACHUSETTS

LONG survival of patients with complete severance of the spinal cord is rarely encountered in civilian life. During the recent world conflict, however, the high incidence of casualties from high-explosive missiles resulted in a moderate number of such injuries. The medical and surgical advances of recent years, together with rapid and efficient evacuation from the field of battle, have greatly increased the initial survival rates of these men. Paraplegia centers established during the war employed new techniques of bladder management, assiduous hospital care and careful medical and physical rehabilitation. These and other factors combined to increase markedly individual and group longevity as compared with the average life span of patients suffering similar injuries during World War I. Coincidentally, an opportunity was provided for the study of an unprecedented number of traumatic lesions of the spinal cord.

This article represents an abbreviated report of observations relating to certain patterns of involuntary activity exhibited by long-surviving patients with complete severance of the spinal cord. A detailed account of these studies is in preparation. The findings seemed of sufficient theoretical and practical significance, however, to warrant publication of a preliminary report.

Heretofore, it has generally been assumed that after recovery from spinal shock, the only patterns of involuntary activity in skeletal muscle groups exhibited by patients with complete severance of the cord are flexor spasms of the lower extremities and the mass reflex—that is, severe flexor spasm accompanied by spinal sweating and certain visceral manifestations. This assumption rests almost entirely upon the work of Head and Riddoch,<sup>1,2</sup> who, in 1917, conducted an intensive study of 8 patients with ver-

sified, anatomic transections of the cord and of numerous other patients with partial cord lesions. Head and Riddoch reported that, in direct contrast to the totally transected group, patients with partial cord damage exhibited exaggerated extensor movements.

Since the publication of this classic study, one of the principal criteria for the establishment of a diagnosis of complete division of the cord has been the absence of extensor spasm in muscle groups below the level of transection. This criterion has been accepted as an all-or-none rule by many neurologists. Fulton<sup>3</sup> makes the following statement:

Instances of spinal paraplegia are seen with complete loss of sensibility below the level of the lesion and yet may have marked extensor spasm if the limbs are manipulated, especially if the leg is elevated from the popliteal space. This is an *unfailing sign of an incompletely divided cord* and may be of value both in diagnosis and prognosis.

Russell Brain<sup>4</sup> endorses the theory that extensor hypertonia depends upon the integrity of the vestibulospinal tracts and that destruction of the latter results in a dominant flexor reflex. "After a traumatic lesion, causing immediate and complete severance of the cord, paraplegia-in-extension never occurs, because the vestibulospinal tract is interrupted from the beginning and as soon as the stage of spinal shock has passed, paraplegia-in-flexion develops." Similar statements are to be found in most neurologic texts.<sup>5-7</sup>

On the Paraplegia Service of the Cushing Veterans Administration Hospital, we have had the opportunity of studying 27 verified cases of complete transection of the spinal cord in white men. The levels of transection ranged from the second to the twelfth dorsal vertebrae. In every case complete examinations could be made two or more years after transection. In 2 men the pattern of involuntary activity in muscle groups below the transected level consisted of flexor spasms alone. Two men exhibited approximately equal flexor and extensor spasms and 19 showed predominant extensor spasms with flexor components. In no patient was extensor spasm alone elicited. Five men were completely

\*From the Paraplegia Service, Cushing Veterans Administration Hospital.

§Fellow, Department of Physiology, Johns Hopkins University School of Medicine; formerly chief of surgery, Paraplegia Service, Cushing Veterans Administration Hospital.

flaccid, and no reflex activity was noted in the musculature innervated below the level of cord section

The following case illustrates a typical progression of reflex activity

CASE 2 J Z, a 22-year-old man, sustained multiple machine-gun wounds on February 3, 1945. He was immediately paralyzed from the level of the nipples downward. X-ray study disclosed compound, comminuted fractures of the second and third dorsal vertebrae and evidence of fragmentation of the neural canal at that level. Exploratory laminectomy on December 4, 1946, revealed a complete

being converted into a rigid pillar. Rigidity of the adductor musculature was a prominent feature of this picture.

Noiceptive stimulation of the plantar and genital areas elicited dorsiflexion of the four toes, with no movements of the hallux, moderate dorsiflexion of the foot and sharp, tugging flexion at the knee and pelvis. Crossed phenomena included plantar flexion of the foot and visible tightening of the anterior and posterior thigh musculature. The abdominal wall was not involved in the flexion reflex. The right lower extremity failed to demonstrate full triple flexion, but was considerably stronger in extensor manifestations than the left.

The superficial abdominal reflexes were absent, and the deep ones were ++ in all quadrants. The knee jerk was ++++ on the right with sustained patellar clonus and

anatomic severance of the spinal cord with a gap between the scarred ends

Involuntary movements of the lower extremities were first noted 20 days after injury, when "someone pulled the hairs along my right thigh and the leg jumped." Bilateral flexor spasms gradually manifested themselves and within 6 months had become quite frequent and vigorous. It became necessary to tie the patient to his bed as a safety measure. Occasional extensor spasm occurred, but it was not until 18 months after injury that the strength and frequency of extension increased. Stepping movements were noted, and sudden over-all rigidity stiffened him out on the bed or slid him out of his wheel chair. Penile erections have occurred frequently since injury, but ejaculation has never been noted.

Neurologic examinations 2 years and 2 months after injury disclosed that extensor spasm, although not precipitated by plantar stimuli, became manifest immediately if the thighs were stroked or squeezed, if pressure were applied at the popliteal region, or if the patient were shifted from a sitting to a supine position. Rigidity was generalized from the level of the xiphoid process caudad and was sustained for approximately 5 seconds. If one lower extremity were elevated by lifting at the popliteal space, initial ipsilateral extension occurred and frequently crossed to the opposite extremity. Rapid lowering of an extended leg evoked severe ipsilateral extensor stiffening, which was invariably crossed. The resultant reflex figure consisted of bilateral extension of the lower extremities, the entire body below the level of transection

+++ on the left. Elicitation of patellar clonus on the left frequently resulted in sustained extensor rigidity of that extremity. Ankle jerks were ++ bilaterally with sustained clonus. Babinski's sign could not be elicited.

## DISCUSSION

An unparalleled opportunity for the study of long-surviving patients with traumatic lesions of the spinal cord has been afforded by World War II, and knowledge of the reflex functions of the cord has recently been further clarified. For example, earlier views regarding the physiology of the "automatic" bladder have been re-evaluated,<sup>7-9</sup> and hitherto unknown facts concerning the sensory capacities of the isolated spinal cord have been reported.<sup>10</sup> It is not surprising, therefore, that an exhaustive study of the reflex patterns exhibited by patients with complete spinal-cord transection reveal data that conflict with previous observations.

Release of the vestibulospinal tracts from suprasegmental control (with a resultant uninhibited flow

of impulses to the extensor muscles) provides a rational explanation for the extensor spasms that may predominate after partial lesions of the spinal cord. It might appear logical to assume the corollary of this hypothesis to be true that complete interruption of the vestibulospinal tracts precludes the occurrence of extensor spasm below the level of the lesion. The preceding case studies are not in agreement with such a hypothesis, however, for it is evident that quite marked extensor patterns may

## SUMMARY

The involuntary-activity patterns of skeletal muscles below the level of the lesion in 27 verified cases of complete spinal-cord transection have been studied. In each case examination was possible at least two years after division of the cord had occurred.

Two patients exhibited flexor spasms alone, 2 showed approximately equal flexor and extensor spasms, and 19 displayed predominant extensor

predominate in subjects with complete division of the spinal cord. In our experience, the most typical sequence of events following cord transection is spinal shock, gradual return of reflex activity, flexor spasm, alternating flexor and extensor spasm, and finally, predominant extensor spasm. Fortunately, severe spasticity of the skeletal musculature can be completely eliminated, in most cases, by anterior rhizotomy.<sup>11</sup> It is probable that the discrepancies between our findings and those of earlier investigators can best be explained by the better physical condition and increased duration of life of present-day patients with complete spinal-cord transection.\*

\*The explanation of the primary extensor manifestations in these patients is not clear. We believe that such reflex responses represent the appearance of primitive, poorly integrated postural activity mediated through the isolated cord, in sharp contrast to the exclusively flexor responses which characterize the early stages of recovery after cord transection and which belong to Sherrington's<sup>12</sup> group of primitive nucleospinal reflexes. It appears that the functional capacity of the isolated cord, if given sufficient time to recover, is greater than has been assumed. An analogy may be drawn to earlier views concerning the capacities of mesencephalic and bulbospinal animals. Recently additional fighting and postural patterns have been demonstrated in these preparations because for the first time it has been possible to maintain them under satisfactory conditions for long periods.<sup>13,14</sup>

spasm with flexor components. Five patients showed complete flaccidity below the level of the lesion.

It is concluded that, although a patient with a complete spinal lesion passes through a period in which flexion reflexes alone are active, he frequently progresses to a stage of activity characterized by predominantly extensor reflexes, amounting in many cases to extensor spasm.

It is evident, therefore, that extensor spasm in skeletal muscles, innervated below the level of transection, is not conclusive proof of an incomplete division of the human spinal cord.

We are indebted to Dr. Donald Munro, consultant in neurosurgery, who has been a source of constant encouragement in the investigation and rehabilitation of the patients studied.

## FATAL ACUTE PANCYTOPENIA FOLLOWING TRIDIONE TREATMENT\*

THOMAS J CARNICELLI, MD,† AND C G TEDESCHI, MD‡

FRAMINGHAM, MASSACHUSETTS

TRIDIONE, since first proposed in 1945 as an anticonvulsant agent, has been generally accepted for the control of petit-mal and major psychomotor attacks. The favor it met with was justified by a number of reports, all claiming the efficiency of the drug in the control of convulsive disorders

and the apparent absence of toxic manifestations. No side effects were seen by Everett and Richards<sup>1</sup> in a large series of animals, including mice, guinea pigs, cats and rabbits, in which the anticonvulsant properties of the new drug were compared with those of Dilantin and phenobarbital, no toxic manifestations were found by Richards and Perlstein<sup>2</sup> in their series of human patients.

TABLE 1 Clinical and Laboratory Data

6	100-103	80	32-60	—	—	—	—	—	—	—	—

and the apparent absence of toxic manifestations. No side effects were seen by Everett and Richards<sup>1</sup> in a large series of animals, including mice, guinea pigs, cats and rabbits, in which the anticonvulsant properties of the new drug were compared with those of Dilantin and phenobarbital, no toxic manifestations were found by Richards and Perlstein<sup>2</sup> in their series of human patients.

The first mention of side effects was made by Lennox,<sup>3</sup> who noticed skin rashes and hemeralopia in some of his cases. This was confirmed by DeJong,<sup>4</sup> who in addition called attention to occasional nausea, drowsiness and a sensation of lightheadedness. These toxic manifestations were considered to be relatively unimportant and not of the nature to justify excessive precaution in the administration of the drug.

The first fatal case of acute aplastic anemia following combined treatment with tridione and hydanto-

in was reported in 1946 by Harrison, Johnson and Ayer.<sup>5</sup> There was a strong suggestion in this case that one or both of these drugs had been instrumental in the development of the blood condition, but it was only after a similar case had been published by Mackay and Gottstein<sup>6</sup> that tridione was re-

garded as the determining factor in the fatal outcome in both cases. The course of events compared exactly in the 2 cases. In the case report of Harrison, Johnson and Ayer<sup>5</sup> a sixteen-year-old girl concurrently treated for a period of six months with tridione and methylphenylethyl hydantoin, began to show increasing pallor, accompanied by a tendency to bruise easily and by the appearance of petechial hemorrhages and ecchymotic areas in the skin. The essential laboratory findings were those of an increasingly severe pancytopenia. None of the agents generally used to stimulate hematopoiesis, including pentnucleotide, crude liver extract, folic acid and transfusions of blood, proved to be of any avail, and the patient died of uncontrollable menorrhagia on the thirty-eighth hospital day. A post-mortem examination confirmed the diagnosis of aplastic anemia. It was estimated that the bone marrow was reduced to a fourth of its presumed normal amount. Foci of hematopoiesis were present in the spleen and in the lymph nodes.

\*From the Department of Medicine and Division of Laboratories, Framingham Union Hospital.

†Chief of the medical staff, Framingham Union Hospital.

‡Pathologist, Framingham Union Hospital.

In the case presented by Mackay and Gottstein,<sup>6</sup> in a twenty-four-year-old woman, evidence of the hematic crisis was delayed but abrupt, ten months after the use of a concurrent treatment with phenobarbital and tridione. Sixteen days after the onset, characterized by headache, weakness and fatigue, the patient died with a typical picture of aplastic anemia that no treatment was able to control. Autopsy revealed extensive hemorrhages throughout the body.

The third fatal case so far reported after tridione treatment occurred in this hospital. A brief report is presented below to emphasize further the hazards that the treatment involves and to offer some suggestions regarding the precautionary measures that must be followed if the use of the drug has to be continued.

### CASE REPORT

G. L., a 19-year-old girl, had been well until the age of 14 years when she developed sudden brief episodes of amnesia that occurred irregularly at intervals of days or months and lasted from a few seconds to a minute. These spells were consistently preceded by an aura, which consisted of flushing or of a tingling sensation of the face. Loss of consciousness, convulsions, falls, tongue biting and incontinence never occurred. On September 26, 1946, the patient was seen by a psychiatrist. Complete physical and neurologic examination

gingival mucosa did not appear to be abnormal. The temperature was 102 F.

Examination of the blood revealed a red-cell count of 2,330,000, with a hemoglobin of 10.5 gm. per 100 cc. and a white-cell count of 1600 with 4 per cent neutrophils, 90 per cent lymphocytes and 6 per cent monocytes. Platelets were rare in the stained film and a platelet count (Rees-Ecker method) yielded 5000 cells. The bleeding time was 71 minutes and the clotting time with standard Corning glass capillary tubes was 4 minutes. The icteric index was within normal limits. The blood Hinton reaction was negative.

The most important features of the clinical course with collateral laboratory findings are presented in Table 1. In spite of intense penicillin treatment the fever persisted, the temperature rising in step-like progression to a maximum of 105°F. on the 5th day. The cause of the fever was never clear, and except for the gingival bleeding and increasing petechial manifestations throughout the body, repeated physical examinations failed to reveal any disease. None of the agents generally used to stimulate hematopoiesis and to stop bleeding, including transfusions of folic acid, liver extracts, Lextron and intensive vitamin treatment (Cevalin and vitamin K), proved to be effective. The picture of pancytopenia persisted with slight variations and daily blood transfusions did not appear to be of any avail other than to raise transiently the level of the hemoglobin and the red-cell count. Reticulocytes could never be demonstrated. The downhill course was further complicated by a menorrhagia which started on the 1st hospital day and became increasingly more severe. Crampy abdominal pains developed, and tarry stools began to appear 1 day before death, which occurred on the 6th hospital day.

Post mortem examination revealed extensive hemorrhages both in the skin and in the internal organs, some of which appeared to be recent and some others older. All organs appeared to be affected, including the serous membranes (peri-

\*Control 32 seconds.

including x-ray investigation of the skull was entirely negative, electroencephalographic studies were also made and interpreted as "nonspecific." She was started on tridione treatment (0.3 gm. three times a day) and elixir of phenobarbital (4 cc. three times a day) on September 26. Examination of the blood on October 17 revealed no abnormalities. The spells became less frequent but still occasionally occurred and when the patient was seen again in early December she was advised to take Dilantin (0.1 gm.) three times a day in place of phenobarbital and to continue the tridione treatment in the amount previously prescribed. This combination proved to be effective and during the month of December the patient had only one spell. On February 18, 1947, she began to notice bleeding from the gums on brushing her teeth and the onset of fatigue. She had been warned to watch for this occurrence and therefore consulted her physician, who, in turn, referred her to a dentist. Since bleeding persisted and became more profuse, hospitalization was recommended for blood studies and treatment. All medications had been suspended when the bleeding was first reported. She entered the hospital 16 days after the onset of bleeding.

The past history was completely irrelevant except for measles as a child. In the family history the only significant data were that the paternal grandmother had died of leukemia and the paternal grandfather of anemia, the type of which was not known.

Physical examination was essentially negative, except for a maculopapular rash of the upper arms and shoulders and numerous fine petechiae over both feet. There was continuous oozing of blood from the gingival margins but the

cardium, pleura and peritoneum), the lungs, the myocardium, the mucosal lining of the large and small bowel and the internal genital organs, which appeared to be the most severely involved. The ovaries were greatly enlarged—being almost the size of a small tangerine—and were deeply infiltrated by blood. More blood was contained in the lumen of the tubes, and through the fimbrial openings about 400 cc. of blood had escaped into the abdominal cavity. Gross examination of the brain revealed a seed-sized hemorrhage in the left thalamus, and a number of punctate hemorrhages of the ring type were further found in the microscopical sections from different portions of the brain. Additional microscopical findings were large foci of extramedullary hematopoiesis in the spleen and in the mesenteric lymph nodes.

The bone marrow was examined in the sternum and in the ribs. The ribs had a dry, honey-combed appearance and were practically devoid of marrow. The sternal marrow was also scanty but showed some redness, and contained 400 red cells per cubic millimeter with 96.8 per cent blast cells, 0.8 per cent promyelocytes, 1.2 per cent myelocytes, 1.0 per cent neutrophils, 0.1 per cent eosinophils and 0.1 per cent basophils, and 1.3 per cent neutrophilic metamyelocytes, and 0.7 per cent polymorphonuclear leukocytes (Fig. 1). No erythroblasts or megakaryocytes could be seen.

### DISCUSSION

In this case, as in the similar 2 cases reported in the literature in which death followed tridione treat-

ment, a condition of aplastic anemia accounted for the fatal course of events. No other factor could be incriminated. As in the case presented by Mackay and Gottstein,<sup>6</sup> the blood condition developed several months after the patient was receiving the medication, the onset was abrupt and sudden and no available treatment could prevent the fatal outcome.

The term "aplastic anemia" carries the implication that the bone marrow has become nonfunctional. That such a concept has to be revised is, however, indicated by the well known fact that the decrease in number of erythrocytes, granulocytes and thrombocytes in the peripheral blood is not con-

FIGURE 1 *Low-Magnification View of the Bone Marrow, Showing Active Hematopoiesis but Predominance of Lymphocytoid Cells, Interpreted as "Blast" Cells*

sistently accompanied by an aplastic bone marrow. Thompson and his associates<sup>7</sup> found marrow aplasia in only 1 of their 13 cases; there are, in addition, a number of cases on record, and certainly a larger number of unrecorded cases, in which the bone marrow appeared to be hyperplastic, with an actual increase of hematopoietic tissue, a decrease in fat spaces and a conversion of fatty marrow of the long bones into an active stage. The conception of a "maturation arrest" or of a "bone-marrow block" has been advanced to explain these cases. The classification of aplastic (refractory) anemia with hypocellular marrow, immature cellular marrow, active cellular marrow, sclerosis of the marrow and megakaryocytic marrow, proposed by Rhoads,<sup>8</sup> still stands.

Mackay and Gottstein,<sup>6</sup> in trying to analyze the toxic effect of the drug, have pointed out the structural affinity of tridione and aminopyrine, the effects

of which on the blood elements are well known. The intimate mechanism through which the drug acts on the hematopoietic system seems, however, to be various. In the case reported above, as in that of Harrison, Johnson and Ayer,<sup>5\*</sup> the drug acted upon the bone marrow, inhibiting cell maturation in all series (aplastic anemia with immature cellular marrow of Rhoads's classification). Instead, in the case of Mackay and Gottstein,<sup>6</sup> the cytotoxic effects of the drug resulted mainly in destruction of blood cells, both red and white (aplastic anemia, with hypocellular marrow, of Rhoads's classification).

In view of the bone-marrow findings and of the foci of hematopoiesis in the spleen and in the mesenteric lymph nodes the question of a possible aleukemic process (aleukemic myelosis), coincident with or precipitated by the drug treatment, arises in the case reported above. The differential diagnosis between aleukemic myelosis and aplastic anemia with hyperplastic bone marrow that in other cases might be considered a matter of academic interest becomes a matter of practical importance in the case under consideration. After thorough study of the blood smears we believe that the possibility of an aleukemic process can be ruled out, since at no time during the course of the disease were immature cells found in the peripheral blood.

With 3 fatal cases already recorded it is apparent that a good deal of precaution should be applied in the use of tridione. Mackay and Gottstein<sup>6</sup> have already stressed the point that the drug should not be administered to any patient who has had blood dyscrasia, severe anemia or hemorrhagic tendencies.

It has been advised also to use the drug in small doses at the beginning and to make frequent examinations to detect the onset of any blood disorders. In view of the possible toxic effects from the use of tridione it is essential that the drug be used only in cases for which it is particularly effective—namely, patients with petit-mal seizures. There is no sufficient evidence in the case reported above that the patient was having this particular type of seizure. The drug has already proved of such value in the control of convulsive disorders that the few fatal cases resulting from its use should not discourage its further administration. Certainly, one might feel safer in prescribing the drug if a new chemical product could be found of equal therapeutic efficacy but deprived of toxic effects, or if some methods could be developed to measure the concentration of the drug in the blood during the treatment and the sensitivity of the patient to the drug itself before the treatment is started.

#### SUMMARY

A fatal case of acute pancytopenia following the use of tridione is reported, with a brief review of 2

\*It is possible that the bone marrow cells that we considered as blast cells corresponded to the cells interpreted by Harrison, Johnson and Ayer as lymphocytes (lymphoidocytes of Pappenheim and Maximow).

other fatal cases so far recorded. A note of caution is sounded regarding the administration of this drug and its potential danger, as well as the necessity of frequent blood examinations. A plea is made to limit the use of tridione to the control of true petit-mal seizures.

## NEUROLOGIC COMPLICATIONS OF TRICHINOSIS\*

## Report of Two Cases

JAMES C. SKINNER, M.D.†

BOSTON

ALTHOUGH increasing attention has been paid to trichinosis in recent years, relatively little has been reported concerning its neurologic complications. Drowsiness, headache, depression and delirium are observed to be common findings. Frank meningeal irritation, hemiplegia, aphasia and other localized neurologic manifestations occur in from 10 to 17 per cent of all cases,<sup>1, 2</sup> but there are often no changes in the cerebrospinal fluid. The manner in which the infestation affects the brain has never been clearly demonstrated, although it is assumed that small cerebral vessels are occluded by the parasite. The prognosis of the cerebral symptoms in this disease is correspondingly uncertain. Indeed, it appears possible for neurologic manifestations to occur with few other clinical signs of the disease.

The following cases illustrate some of the difficulties encountered in diagnosis.

**CASE 1.** S. T., a 60-year-old Polish born woman was admitted to the hospital on October 29, 1946. She had been well until about 2½ weeks before admission when mild nausea and pain in the lower abdomen developed. Two weeks before admission she and her family noted the onset of periorbital edema with retrobulbar pain. This was not accompanied by fever, rash or local inflammation. The periorbital edema increased rapidly for 2 or 3 days, until both eyes were swollen shut. Ten days before admission generalized myalgia, particularly in the legs and anorexia developed. The swelling of the eyelids disappeared after 5 days, but 2 days later the temperature rose to 104°F. and chills, nausea and vomiting occurred. Despite the administration of sulfonamides by a physician the patient became progressively weaker and anorexic.

One week before admission she first became incontinent, appearing to show no concern over wetting or soiling the bed. She developed increasing apathy, and although she continued to recognize her family and friends, she became increasingly confused and was stated to have thrown her arms about in purposeless movements.

A further history obtained from the patient and from her relatives revealed the fact that she had obtained a portion of a pig from friends, about 4 or 5 weeks before admission and had eaten a rather large amount of the meat. Her family refused to touch the pork which had tasted spoiled to them. The friend who owned the animal was said to have suffered from periorbital edema and nausea several days before the onset of the patient's illness.

\* From the Neurological Unit, Boston City Hospital and the Department of Neurology, Harvard Medical School.

† House officer, Neurological Service, Boston City Hospital.

Physical examination revealed an obese woman apparently aware of her surroundings but rather apathetic. The skin showed the changes produced by mild dehydration. There was no lymphadenopathy. No muscular soreness could be elicited. The lungs were clear to percussion and auscultation. The heart was not enlarged. There was a Grade I diastolic murmur at the apex. The liver was palpated one fingerbreadth below the costal margin.

The pulse was 112, and the blood pressure 120/82.

Neurological examination showed the following abnormalities. The patient lay quietly in bed with her eyes closed. Occasionally but not consistently she responded to simple commands if they were repeated several times (whether in English or Polish seemed unimportant). Any movement was soon discontinued as though in weariness or apathy. Orientation in time and space was apparently excellent and although she did not initiate conversation either with the examiner or with her family, on further examination this fact was deemed to be more the result of drowsiness and apathy than true aphasia.

The left arm and left leg were considered to be slightly flaccid as compared with the right arm and right leg, but all reflexes were found to be normal at that time. There was some slight nuchal rigidity.

Examination of the urine showed 20 to 30 white cells per high power field. Examination of the blood disclosed a red cell count of 4,380,000 and a white-cell count of 12,250 with 53 per cent neutrophils, 38 per cent lymphocytes and 5 per cent eosinophils. Lumbar puncture demonstrated an initial spinal fluid pressure equivalent to 110 mm. of water and xanthochromic fluid containing 700 crenated red cells per cubic millimeter with a total protein of 11 mg. and a sugar of 85 mg., and a chloride of 708 mg. per 100 cc. Three days later a second lumbar puncture again showed a yellow fluid with a pressure equivalent to 140 mm. of water that contained 540 fresh red cells per cubic millimeter with a total protein of 11 mg. per 100 cc. and a gold sol curve of 0001110000. The spinal fluid Hinton and Wassermann reactions were negative. An electrocardiogram revealed myocardial disease, the T waves being inverted in Lead I, diphasic in Leads 2 and 4, and of low voltage in Lead 3.

Six days after admission, the reflexes in the right arm and right leg were found to be slightly more active than those on the left and the right plantar response was equivocal. Two days later the right plantar response was definitely extensor. A Trichinella antigen skin test on the 7th hospital day was equivocal but when repeated on the 8th day it was definitely positive. The patient at that time was thought to be of normal mental status. On the 22nd hospital day the daily differential blood smears showed a rise in the eosinophil count to 13 per cent and thereafter during the patient's stay remained at about this level with a continuing relative lymphocytosis. A number of examiners agreed that the muscles were neither indurated nor tender. Nevertheless a small muscle biopsy from the left medial gastrocnemius was taken on the 8th hospital day and upon section showed several fine examples of freshly encysted trichinae. The continued tachycardia

caused some concern, and mobilization was made extremely gradually. Late in the convalescence pain developed upon deep breathing just over the two lower ribs on the left. X-ray study showed some consolidation in that area, and the patient was treated successfully with penicillin and discharged. She continued to improve rapidly, although on discharge 5 weeks after admission she still had an extensor plantar response and increased deep tendon reflexes on the right.

**CASE 2** W K, a 40-year-old toolmaker, was admitted to the hospital on October 31, 1944. He had been well until 3 weeks before admission, when he noticed the onset of "sick feelings," nausea, chilly sensations, a temperature of 101°F and a slight nonproductive cough. Within a day, increased nausea and vomiting developed, and he continued to vomit intermittently. During the same period he also experienced abdominal discomfort, diarrhea and mild pains in the muscles, including the wrists, arms, legs and back. The exact order of the appearance of these symptoms was not clear. The symptoms progressed until 5 days before admission, when they became so severe that he was forced to leave his work and spend the day in bed. It was then that he first noted "spots before the eyes," conjunctivitis, increased lacrimation and periorbital edema. He drank some tea and whisky and remained in bed until the night before admission, when his family physician recommended hospitalization.

The diagnosis of trichinosis was immediately suspected, and on questioning the patient stated that the only pork that he had consumed recently had been obtained at a restaurant a few days before the onset of the symptoms and that several other men who had eaten at the same restaurant had identical, although less severe, symptoms.

The past, family and social histories were not contributory.

Physical examination was entirely negative except for conjunctivitis, periorbital edema and a blood pressure of 100/70. Neurologic examination was negative, although the patient was noted to be restless and apprehensive about his condition.

Examinations of the blood showed a white-cell count ranging between 11,000 and 14,500, with 44 per cent eosinophils, which gradually increased to 64 per cent during the 3 weeks that the patient remained on the ward. The urine was normal. Lumbar punctures on the 19th and 24th hospital days were normal in all respects. Electrocardiographic tracings taken 2 and 8 days after admission showed sinoauricular tachycardia, low voltage and low origin of the ST segments in all leads. These were interpreted as showing myocardial damage.

On the 4th day the patient showed increased restlessness, and his movements were said to be jerky. He demonstrated great apprehension and anxiety, and in view of these complaints he was given paraldehyde. Despite medication he became increasingly restless, noisy and disoriented, and it was necessary to place him in restraint. He showed no tremor of the hands or tongue suggestive of delirium tremens. Infusions were given, and during the night 0.25 gm of luminal sodium was required to quiet the patient. The next morning the blood pressure was unobtainable and the patient's condition was critical. He then began steadily to improve. After the next 4 or 5 days it was noticed that the patient had difficulty in walking, and neurologic examination on the 20th hospital day demonstrated a slight left hemiparesis. There was an extensor plantar response on the left and a positive Hoffmann reflex in the left hand, together with slightly more active knee and ankle jerks in the left leg. The patient was noted to drag the left leg in walking, and when it was extended and elevated it "drifted" downward in marked contrast to the right leg. Position sense was also found to be impaired in the fingers and toes on the left. On the 25th hospital day the reflexes were slightly more active on the left than on the right, and an extensor plantar response was still present on the left side.

During the following 4 days, until discharge 1 month after admission, he showed gradual improvement in his ability to walk. His apprehension and anxiety disappeared completely.

Five months later the patient was readmitted to the hospital for incipient delirium tremens, and at that time it was noted that the gait was unsteady, difficulty apparently being limited to the left leg. Vibration and position senses were impaired in the left leg, with hypesthesia, and there was an extensor plantar response in the left foot.

Unfortunately, no muscle biopsy was taken on either of the admissions, and the diagnosis of trichinosis must therefore remain presumptive, although there seems little reason to doubt the nature of the disease in the presence of such a characteristic history and with the progressive increase in the eosinophilic differential count.

## DISCUSSION

Since an adequate review of the literature pertaining to the manifestations of infection by *Trichinella spiralis* may be found in Gould's<sup>1</sup> excellent monograph, no extensive recapitulation need be attempted in this report. The cerebral lesions were described by Most and Abeles,<sup>3</sup> who found three types of microscopic changes in the brain at autopsy: the presence of granulomatous nodules, described as being a dense collection of cells occurring most frequently throughout the subcortical white substance and consisting of lymphocytes, plasma cells and a third large cell with a vesicular, polymorphous nucleus, with another type of nodule consisting mainly of microglial elements, the appearance of the parasite in the parenchyma of the brain, the parasites being the filariform larvae and being found in the nodules described above, the evidence of pathologic alterations in and around the blood vessels—there was extensive perivascular infiltration with fibroblasts, plasma cells, polymorphonuclear cells, gutter cells and small darkly staining cells resembling lymphocytes. The authors also remarked upon the numerous small hemorrhages in the periventricular areas below the ependymal layer. No large hemorrhages were noted.

The disordered mental state and the residual neurologic signs were the remarkable features of the 2 cases reported above. In Case 1 the mental status was remarkable for the severe depression, which, upon gradually clearing, disclosed a deep lethargy that persisted for some days longer. In Case 2, the picture was one of an acute delirium so similar to that encountered in acute and chronic alcoholism that the patient was thought for a time to be suffering from delirium tremens. It is also interesting that the delirium occurred three weeks after the onset of symptoms and lasted only two days, although the patient was said to have been restless and apprehensive during the earlier weeks. In the first case reported by Most and Abeles<sup>3</sup> the patient was described as being severely depressed, with clouded mentality and some evidence of mild disorientation. Their second patient was also disoriented and to a greater extent, with severe difficulty in recent and remote memory. The lethargy and depression are particularly interesting as special manifestations of only a limited number of diseases and are not so nonspecific as simple delirium. In the large number of cases reported by Sheldon<sup>2</sup> in the Wolverhampton epidemic, depression and lethargy were common to almost all patients. It is extremely difficult to decide whether this peculiar mental state results from damage to the nervous system or

whether it is only a concomitant effect of severe illness. It is of some significance, however, that these symptoms have seldom been noted in cases that presented no focal neurologic signs. That this is not simply a measure of the severity of the general infection is indicated by the cases reported by Spink,<sup>4</sup> in many of which the infection was fatal without neurologic involvement. It therefore seems reasonable to postulate diffuse damage to the brain in at least some cases since the pathological material in the cases of Most and Abeles<sup>2</sup> demonstrated widespread affection of nervous tissues. In the case reported by Stern and Dancy,<sup>5</sup> the patient had shown severe psychotic tendencies before the onset of trichinosis, and it seems most reasonable to assume that the major psychosis that appeared with the height of the infection was only the result of a severe sickness.

The signs of focal damage to the nervous system gave certain evidence of central-nervous damage in the cases reported above. In Case 1 there was a mild hemiplegia on the right with an extensor plantar response on the same side that could still be elicited upon discharge five weeks after admission. The patient in Case 2 showed a left hemiplegia with loss of position and vibration sense in the extremities, together with an extensor plantar response. On readmission five months later some ataxia, with loss of position and vibration senses, and the extensor plantar response were still present. The lesion in the right cerebral cortex was thus of a destructive nature rather than a transitory vascular or toxic change. In Spink's<sup>4</sup> fourth case, a right hemiplegia was present together with aphasia, and these symptoms were of sudden onset. It seems necessary to postulate a sudden vascular occlusion to account for such signs. One of the cases of Most and Abeles had shown a hemiplegia, and the other showed absent deep tendon reflexes in the lower extremities with absent biceps reflex in the upper extremities. No vascular occlusion was found, but there was abundant evidence of perivascular infiltration, generalized engorgement and hyperemia. Absence or decrease of the tendon reflexes is a common neurologic finding in cases of trichinosis, as in Merritt and Rosenbaum's<sup>6</sup> second case, and probably indicates damage to the spinal cord. Sheldon<sup>7</sup> estimates that 17 per cent of all cases seen in the epidemic in Wolverhampton gave evidence of focal neurologic damage. Some of his patients showed cerebellar signs, and indeed in several cases dizziness, cerebellar ataxia and nystagmus were the presenting symptoms and signs before any evidence of general trichinosis appeared.

Case 1 presented three unusual features. In the first place, repeated eosinophilic counts during the

entire period of observation failed to reach the high level commonly reported. In addition the count was slow in rising, in spite of proved heavy infestation. Gould<sup>1</sup> remarks that this is a poor prognostic sign. Secondly, although no muscular tenderness or induration could be established, even though it was especially sought, a biopsy taken from the muscle most readily accessible — the gastrocnemius — demonstrated without difficulty the presence of the parasite. This finding indicates that the absence of persisting induration and tenderness does not exclude infection. Thirdly, on two successive occasions lumbar punctures disclosed spinal fluid containing 500 to 700 red cells per cubic millimeter and showing xanthochromia. It did not appear possible for the blood to have been introduced by the lumbar-puncture procedure. From the findings of Most and Abeles it appears that multiple periventricular hemorrhages had occurred.

In view of the high liability to epilepsy resulting from other parasitic infection of the brain, particularly from cysticercosis, it is remarkable how seldom this complication is reported after trichinosis. Dandy<sup>7</sup> has reported a case followed by grand-mal seizures ten years later. The cerebral lesions in cysticercosis, however, are reported to be more superficial than those of trichinosis, and the lessened liability may arise from this difference. There is much need for further pathological study and above all for wider recognition of the fact that neurologic signs and symptoms of a protean type are a frequent result of *Trichinella* infestation.

### CONCLUSIONS

The cases presenting cerebral involvement in trichinosis reported above indicate that the disease must be suspected in unexplained apathy and stupor with transient signs of damage to the central nervous system. The characteristic history of ingestion of suspected pork followed by periorbital edema, diarrhea with muscular pains and tenderness is occasionally lacking. Absence of persisting muscular tenderness and induration does not negate heavy muscular infestation, and the eosinophilic count may not be greatly changed.

## ACANTHOSIS NIGRICANS\*

## Report of a Case Associated with Thyroid Cancer

WILLIAM H KAUFMAN, M D,† AND ROBERT F TILLEY, M D ‡

CHARLOTTESVILLE, VIRGINIA

**A**CANTHOSIS nigricans associated with cancer of the thyroid gland has apparently never been recorded in human beings. The following case is therefore of particular interest.

A 33-year-old Negress was admitted to the Surgical Service of the University of Virginia Hospital on February 1, 1947, complaining of shortness of breath of 1 month's duration.

In December, 1944, the patient had had a rapid onset of tremulousness, palpitation, dysphagia, exertional dyspnea, progressive weight loss and painless tumor formation in the anterior portion of the neck. On February 26, 1945, she had been admitted to another hospital, where the thyroid gland was found to be enlarged, and the basal metabolic rate in-

gressive dysphagia, dysphonia, exertional dyspnea, anorexia and weakness. On admission she was able to swallow only fluids.

The patient had always been obese. Facial hirsutism and hyperpigmentation had been present since girlhood. An appendectomy had been performed in 1936. Routine blood serologic tests for syphilis were repeatedly positive in May, 1942, when a diagnosis of late latent syphilis was made. Subsequently the patient received inadequate treatment with arsenicals and bismuth. The menstrual history was normal.

Hirsutism and obesity were prominent among female relatives on the maternal side of the family. The patient's 5-year-old daughter had intense facial hirsutism. There was no family history of cancer and no past or family history of cutaneous disease.

The patient was extremely obese, weighing 289.5 pounds (131.5 kg). There were numerous long, silky, lanugo hairs on the upper lip and on both sides of the face. At the base of the nose there were two smooth, oval, hyperpigmented, macular patches extending over to the adjacent infraorbital regions, each measuring 4 cm in diameter. A striking pigmentary eruption was distributed in the natural folds of the skin of the neck, axillas, inframammary and inguinal regions, cubital and popliteal spaces and gluteal cleft, with velvety, hyperpigmented papules and verrucous lesions aggregated into patches arranged parallel to the long axis of the skin folds (Fig 1). There were large, thick hyperkeratoses on the soles. The mucous membranes, fingernails and toenails were normal. A large, fixed, smooth, nontender, indurated mass occupied the whole anterior portion of the neck in the submental and thyroid regions. The mass effectively limited motion of the head and neck. There was a well healed thyroidectomy scar. Movement of the right side of the thorax was limited, with impaired resonance and diminished to absent breath sounds over the entire right lung. Examination of the abdomen was not satisfactory because of extreme obesity, an operative scar of the right rectus muscle was present. No abdominal masses were felt. The liver and spleen were not palpable. There was slight pitting edema over both tibias.

The temperature and pulse were normal, and the respirations were rapid and labored. The blood pressure was 150/80.

Routine laboratory studies showed nothing remarkable. The blood Wassermann and Kahn reactions were repeatedly positive. Owing to the patient's poor general condition, a lumbar puncture was not performed. A Robinson-Power-Kepner<sup>1</sup> test for adrenal cortical insufficiency was within the limits of normal — although the total volume of urine voided during the night was greater than any one of the hourly specimens obtained during the morning, procedure 2 of the test gave a value of 73.5, which is considered normal.

A roentgenogram of the chest showed massive effusion in the right pleural cavity, with swelling of the soft tissues posterior to the trachea opposite the seventh cervical and first thoracic vertebrae. After the withdrawal of 2400 cc of sanguineous fluid, repeated roentgenograms of the lungs demonstrated an area of lobulated, homogeneous density extending throughout the posterior portion of the right lower lung field. This was considered to represent metastatic tumor.

The patient had decided respiratory discomfort throughout her stay in the hospital. She was relieved by six thoracenteses in the first 10 days, with withdrawal of a total of 4460 cc of sanguineous fluid from the right pleural cavity. Examination of a centrifuged specimen of this fluid disclosed no tumor cells. Laryngoscopic examination showed extension of the tumor tissue into the left ventricular fold, with resultant fixation of the left true and false vocal cords. The right side was not involved.

Histologic examination of a specimen of skin from the posterior cervical region revealed the characteristics of

FIGURE 1 Cutaneous Lesions of Acanthosis Nigricans, Showing Hyperpigmentation and Verrucous Changes

creased. A diagnosis of hyperthyroidism was made, and a subtotal thyroidectomy performed. A large colloid cyst was found occupying the left lobe of the thyroid gland. There were several smaller, similar cysts in the right lobe. Four fifths of the left lobe and three fourths of the right were removed. Microscopical study of the tissue disclosed the presence of cancer. Postoperative roentgen-ray therapy consisted of 2400 r to the thyroid region, divided into fifteen treatments. In January, 1946, a little over 1 year after the onset of the illness, the patient noticed small, rough, dark, warty, symptomless papules in the axillas. She paid little attention to these lesions, which increased only slightly in size and number. At no time was she aware of similar lesions elsewhere on the body. After the last x-ray treatment in September, 1946, she was asymptomatic until January, 1947, when the mass in the neck returned and she developed pro-

acanthosis nigricans (Fig 2 and 3). There was distinct papillomatosis of the cutaneous surface with decided hyperkeratosis. An irregular acanthosis with many finger-like rete ridges was present, although most of the prickle-cell layer was relatively thin and atrophic. The depressions between the epidermal projections were filled with keratin. There was dense melanin pigmentation of the basal cells. The long, narrow papillary bodies contained moderate numbers of pigment-laden chromatophores. The cutis showed no abnormal changes.

Histologic examination of tissue obtained from the thyroid gland showed a malignant tumor composed of broad sheets of spindle-shaped cells containing large vesicular nuclei. These cells varied somewhat in size and form with no particular pattern of growth. Numerous mitotic figures were present. There were many large blood spaces in which the tumor tissue was in direct contact with the blood stream. No recognizable thyroid tissue was seen. On the basis of cell type, this tumor was considered to be mesoblastic in origin. The histologic diagnosis was anaplastic malignant tumor probably of mesoblastic origin.

The patient was given deep filtered roentgen ray therapy in divided doses for a total of 4050 r to the anterior and posterior aspects of the right side of the thorax. Treatment resulted in moderate relief of malaise and respiratory difficulty.

FIGURE 2. Photomicrograph of Skin from the Posterior Cervical Region Showing the Characteristic Structure in Acanthosis Nigricans

Because of previous treatment no x ray therapy was given to the mass in the neck.

During hospitalization the cutaneous eruption showed increase in pigmentation. The patient was instructed to return in 1 month after discharge from the hospital. It was later learned from her physician that she had died suddenly at home of a pulmonary hemorrhage 47 days after discharge.

#### DISCUSSION

Curth's<sup>2</sup> recent review has contributed greatly to a better understanding of the nature of this unusual pigmentary disorder of the skin.

Acanthosis nigricans may be confused clinically with Addison's disease, hemochromatosis and arsenical pigmentation. The clinical and histologic features of these diseases have been described in detail by Montgomery and O'Leary.<sup>3</sup>

The cause of acanthosis nigricans remains unknown. The disorder has been reported in association with a number of conditions, affecting directly or indirectly the chromaffin and sympathetic systems. Among the conditions supposedly related to the cause are metabolic disturbances, toxins, endocrine diseases, tuberculosis, syphilis, congenital

abnormalities, hereditary factors and inflammatory and traumatic lesions of the stomach and chromaffin systems. Curth's<sup>2,4</sup> studies suggest a genetic relation between acanthosis nigricans and certain types

FIGURE 3. Enlargement of a Portion of the Section Shown in Figure 2. The hyperkeratosis, acanthosis and pigmentation are striking.

of cancer, and a common origin for both the benign and the malignant forms of the disease.

The site of the associated primary cancer is almost invariably in the abdomen. Curth<sup>2</sup> found 92.6 per cent originating in the abdomen, the majority of which were located in the gastrointestinal tract. Other reported cases arose from the uterus, chorion and liver.

In some cases the primary site could not be determined. Questionable renal, esophageal and pancreatic carcinomas have been reported. In some cases of acanthosis nigricans the primary tumor was found in the mediastinum, lung and breast. A case in a dog with medullary carcinoma of the thyroid gland, with metastasis to the lung, liver, kidney and lymph nodes, was reported by Schindelfer.<sup>5</sup>

Curth believes that disturbances of the thyroid gland are frequently seen with acanthosis nigricans. Masson and Montgomery's<sup>6</sup> and Curth's patients had thyroid adenomas. These findings may be coincidental.

It is believed the patient in the case reported above had a primary malignant tumor of the thyroid gland. The onset of the disease and the clinical course suggested an origin in the thyroid gland, with metastasis to the lung. Unfortunately, an autopsy was not performed.

Malignant mesoblastic tumors of the thyroid gland appear to be infrequent. Many tumors described as sarcomas are evidently highly anaplastic carcinomas. Ewing<sup>7</sup> regards the mesoblastic origin of most of the sarcomas reported in the literature as highly improbable, and believes that the occurrence of true thyroid sarcoma in man still requires demonstration.

There is a widespread belief that adrenal disease or dysfunction participates in the production of pigmentary changes in acanthosis nigricans. Curth,<sup>2</sup> in a comprehensive review, has considered the existing evidence, which consists of post-mortem findings of involvement of the adrenal gland by metastatic cancer in cases of the so-called "malignant type." Metastases to the adrenal glands are apparently of no etiologic significance, since they occur in only a small number of these cases, and not at all in those unassociated with cancer.

In the case reported above, the presence of a latent syphilitic infection was not considered significant. The patient's obesity and hirsutism were evidently of familial origin, although an endocrine cause could not be excluded without post-mortem examination.

In this patient, as in 2 other cases reported from this clinic,<sup>8,9</sup> there was no evidence of adrenal cortical insufficiency as measured by a test of urinary sodium chloride excretion.

The cutaneous eruption and the malignant tumor are usually discovered at the same time, but the

skin changes may precede or follow detection of the cancer.<sup>2</sup> Since the cutaneous alterations are more easily perceptible than the tumor, their earlier recognition may be only apparent.

Exceptionally, as in the case reported above, the eruption follows the appearance of cancer. The explanation may lie in accessibility of the tumor for diagnosis or in poor observation on the part of the patient.

#### SUMMARY

A case of acanthosis nigricans occurring in association with a malignant tumor, probably carcinoma, of the thyroid gland in a thirty-three-year-old Negress is reported.

The literature regarding this unusual pigmentary disorder of the skin is briefly discussed.

## MORPHINE HYPERSENSITIVITY IN KYPHOSCOLIOSIS\*

KERMIT H. KATZ, M.D.,† AND HAROLD L. CHANDLER, M.D.‡

BOSTON

THE benefits derived from the therapeutic use of morphine in a wide variety of clinical disorders are well appreciated and properly exploited by physicians. At the same time it is recognized that a small but important group of diseases may be aggravated by morphine. This phenomenon may be entirely separate from any individual allergic reaction and applies, potentially, to all persons suffering from such diseases. Mechanical obstruction in the bronchial tree, bronchial asthma and myxedema represent common examples of diseases falling within this category in which the use of morphine is contraindicated.

Much less well known as a serious contraindication to the use of morphine is heart failure asso-

ciated with, or due to, kyphoscoliosis. Two recently encountered cases (1 fatal) of such a reaction to ordinary therapeutic dosage are reported.

#### CASE REPORTS

**CASE 1** J. R., a 49-year-old hotel watchman, re-entered the Boston City Hospital in May, 1946, with the complaint of swelling of the legs.

At the age of 7 years a heavy iron gate had fallen on the patient, fracturing the spine and causing paralysis of the lower half of the body. He required hospitalization for a prolonged period and later wore a back brace for 7 years. As a result of the accident he had a marked "hunch-back" deformity. The patient subsequently enjoyed excellent health until his 48th year, when he began to experience dyspnea on ordinary exertion. In April, 1945, he developed a respiratory infection and was admitted for the first time to the Boston City Hospital. At that time he was found to have kyphoscoliotic heart disease, with pulmonary edema and lobar pneumonia. X-ray study of the chest showed consolidation of the right lung due to pneumonia, and marked kyphoscoliosis. The vital capacity was 700 cc. and 500 cc. on two examinations. Treated with penicillin, later supplemented by digitals and mercurial diuretics, the patient made slow but ultimately satisfactory progress, and was discharged after 6 weeks' hospitalization. In March, 1946, dyspnea returned and was soon followed by the development

\*From the Department of Medicine, Boston University School of Medicine, and the Fifth and Sixth (Boston University) Medical Services, Boston City Hospital.

Presented in part at a meeting of the New England Heart Association, Boston, January 27, 1947.

†Assistant professor of medicine, Boston University School of Medicine; assistant director, Fifth and Sixth Medical Services, Boston City Hospital.

‡Assistant in medicine, Boston University School of Medicine; chief resident physician, Fifth and Sixth Medical Services, Boston City Hospital.

of massive edema of the legs and enlargement of the abdomen Two days prior to re-entry urinary retention developed

Physical examination revealed a poorly nourished deformed man who was orthopneic and coughing frequently. The lips were cyanotic. There was marked thoracic kyphosis and scoliosis to the right, associated with a pigeon-breast deformity of the chest. Numerous rales were heard throughout both lung fields. The heart borders could not be satisfactorily outlined by percussion. The cardiac rate was 125, the heart sounds were of good quality with accentuation of the pulmonary second sound. There were no thrills or murmurs. The abdomen was distended and there was tenderness over the liver shifting dullness was elicited. The urinary bladder was palpated almost to the level of the umbilicus. The prostate gland was enlarged. Edema of the legs was marked. The fingers showed slight clubbing.

The respirations were 30 per minute. The blood pressure was 120/90 in both arms.

Very little benefit resulted from the use of oxygen, digitalis, theophylline and mercurial diuretics. Cyanosis, orthopnea and cough persisted. The patient was very restless and being unable to void, required catheterization frequently. At 7:15 p.m. on the 6th hospital day 10 mg. of morphine sulfate was given subcutaneously in preparation for catheterization. This was the first time the drug was used. In 15 minutes the respirations diminished to 2 per minute. Continued use of oxygen and frequent administration of caffeine and Coramine temporarily increased the respirations to 10, but the patient became comatose. At 8:00 a.m. on the 7th hospital day the respirations were deep and irregular, the rate being 4 per minute. The blood pressure fell to 70/0. The pulse became increasingly rapid and thready. At noon the patient expired.

CASE 2. N.F. a 65-year-old housewife entered the Boston City Hospital on September 6, 1946 with the complaint of shortness of breath and swelling of the legs.

The patient had apparently been in good health until 6 months previously, when she began to note dyspnea on exertion. This progressed in severity until it interfered with her usual household activities. About 1 month prior to admission edema of the legs had developed and further interfered with her activities, the patient being finally restricted to bed and a chair. Shortly before admission she began to cough because of this and the dyspnea she was unable to sleep at night. There was no history of symptoms referable to the gastrointestinal or genitourinary system.

Physical examination revealed an obese woman sitting up in bed who was orthopneic and apparently acutely ill. The skin and mucosae were slightly cyanotic. The retinal vessels showed increased tortuosity and arteriovenous nicking. The neck veins were distended. There was moderate dullness over both lung bases with numerous medium rales audible during inspiration over the lower halves of both lungs. The heart was moderately enlarged to percussion, the border of cardiac dullness extending to both the left and the right. The cardiac rate was 98 per minute, with a regular rhythm. The heart sounds were of good quality with accentuation of the pulmonary second sound. Loud systolic murmurs were heard over the mitral valve and aortic valve areas. There was no thrill or friction rub. The abdomen was obese and slightly distended. The liver and spleen could not be felt. Both legs showed marked pitting edema with superficial maceration of the skin. The vital capacity was 1100 cc. A x-ray study of the chest revealed thoracic scoliosis to the right side, cardiac enlargement and pulmonary congestion.

The respirations were 26 per minute. The blood pressure was 260/110 in both arms.

The patient was digitalized within 24 hours, and initially showed diminution in the pulmonary congestion. However, at midnight of the 3rd hospital day she became more acutely ill manifesting severe dyspnea, cough and increased cyanosis. Oxygen was administered, and theophylline given intravenously. At that time 10 mg. of morphine sulfate was also given subcutaneously. An hour later the patient was found to be comatose. Respirations were deep and regular, the rate being 5 per minute. On further administration of oxygen and with frequently repeated doses of caffeine and Coramine there was slow but gradual improvement in the respiratory rate and general condition. Twenty-four hours later the patient was alert and essentially symptom free. On the 6th hospital day a test dose of 4 mg. of morphine sulfate was given subcutaneously. Over a period of 2 hours the

respirations declined from 26 to 16 per minute and became Cheyne-Stokes in character. Morphine was not administered again.

## Discussion

Two recently published reports have directed attention to the untoward effects of narcotic drugs in depressing the respirations of patients with kyphoscoliosis. In the course of a study of the decrease in functional capacity of the lungs and heart resulting from deformities of the chest, Chapman, Dill and Graybiel<sup>1</sup> observed two critical reactions—one resulting from Pantopon, and the other from morphine. Daley reported 3 patients whose deaths while in cardiac failure were precipitated by the administration of morphine. In 2 cases fatal respiratory depression occurred one hour after the use of morphine in a dosage of 15 mg. In the third case, only 5 mg. was used, but this patient—who suffered, in addition, from diffuse bronchial infection—died seventy-five minutes later with signs of acute respiratory depression.

It has been shown that persons with kyphoscoliosis may suffer from a combination of handicaps, all of which contribute to produce increasing anoxia. The skeletal deformity limits the motion of the ribs and leads to inefficient action of the intercostal muscles and the diaphragm.<sup>2</sup> Compression of the lung on the concave side of the deformity and emphysema on the convex side further reduce the vital capacity, and at the same time diminish the total effective surface for transalveolar gaseous exchange. The result of these skeletal, muscular and pulmonary abnormalities is diminished oxygen saturation of the arterial blood. With the additional handicaps of cardiac failure, respiratory infection or diminished oxygen content in the inspired air (as with inhalational anesthesia or exposure to high altitudes) respiratory embarrassment may become extreme.

The effect of morphine in such situations, apparently, is occasionally disastrous. As in the 2 cases reported above and the others referred to, asphyxia of the patient occurs from one or more of the following effects: a central depressant action on respiration, a depression of cough reflex, a tendency to accentuate bronchial spasm through its cholinergic action and a general hypnotic and pain-relieving action resulting in generally diminished muscular tone.

In normal subjects the administration of carbon dioxide stimulates both the depth and the rate of respiration. After morphine the inhalation of carbon dioxide stimulates the depth rather than the rate.<sup>3</sup> In kyphoscoliosis complicated by some additional condition interfering with pulmonary ventilation, if the depth of respiration is already maximal and fixed, the effect of a lowered respiratory rate induced by morphine can only be one of increased anoxia. The work of Peterson, Bornstein and Jasper<sup>4</sup> indicates that when there is a diminution of the oxygen

available to the pulmonary capillary blood, any drug that blocks pain sensitivity or induces bodily relaxation and general loss of tone results in shallow breathing, with lower oxygen saturation of the arterial blood

We do not believe that the exaggerated effect from morphine is in any way specific for patients with kyphoscoliosis. Our experience suggests that any patient suffering from long-standing lung disease with pulmonary decompensation complicated by heart failure presents similar predisposing handicaps, which might make the added effects of morphine lethal. A sampling of recent case records at the Boston City Hospital of patients suffering from chronic cor pulmonale without kyphoscoliosis lends further support to the impression that these patients are often adversely affected by morphine. These records show numerous cases of severe respiratory depression following the use of such medication in therapeutic dosage. Spain and Handler<sup>6</sup> indicate that they became aware of this hazard during their review of 60 cases of cor pulmonale, and they warn

against the use of narcotic drugs in patients suffering from this disease

### SUMMARY

Two cases exemplifying the adverse effect of morphine on kyphoscoliotic patients with pulmonary cardiac failure are presented. The major physiologic and pathologic factors in the causation of this sensitivity are discussed. It appears probable that persons with decompensated cor pulmonale, but without kyphoscoliosis, will show a similar sensitivity.

## MEDICAL PROGRESS

### ABDOMINAL SURGERY

ARTHUR W. ALLEN, M.D.\*

BOSTON

**D**URING the past year, the literature regarding surgery involving the abdominal region has been voluminous. Many studies pertaining to important variations in anatomic arrangements have been made. Lesions related to congenital defects and their effect on surgical conditions within the abdomen are significant. Detailed follow-up reports concerning life expectancy, especially in patients with malignant tumors, are helpful. Comparative results of the surgical treatment of common disorders in successive years, showing the marked improvement in morbidity and mortality, are impressive. Only articles giving new technics or approaches to usual conditions and those relating to rare disorders can be stressed in this report for lack of space. Some interesting reports are not mentioned either because the subject has been discussed in recent progress reports or for reasons given above. Tribute is due the numerous authors who are contributing to the advance of surgery through their publications.

#### THE ABDOMINAL WALL

Singleton,<sup>1</sup> who was one of the rare surgeons of our time interested in teaching applied anatomy, has left behind a fine contribution on abdominal in-

cisions. He has long championed anatomic approaches to the abdominal viscera and firmly believed that the average surgeon gave this important subject too little thought. His last article is well illustrated and will be a helpful reference. He advocates long, oblique incisions extending well into the flanks, which allow the lateral muscles to be separated in the direction of their fibers while the strong rectus muscle is freed from its fascia and retracted without transection. Excellent exposure to the more remote areas of the abdomen can thus be obtained with little risk of dehiscence or post-operative hernia. The extra time involved in making these approaches and closing the defects seems warranted on the basis of his comparative studies.

Gurd<sup>2</sup> gives a good description of the transverse abdominal incision. He believes that most surgeons do not understand the principles of such approaches and considers transection of the rectus muscles, either 2.5 cm above or 2.5 cm below the umbilicus, to be correct. Attention is called to the importance of separating the lateral muscles of the abdominal wall in the direction of their fibers. Care that the nerve supply be visualized and that not more than one of the lateral nerves be severed is stressed.

Wiley and Sugarbaker<sup>3</sup> have made a comparative study of the use of steel-wire, catgut and silk-layer

\*Lecturer in surgery, Harvard Medical School; chief, East Surgical Service, Massachusetts General Hospital.

closure in a small group of cases. Steel wire was most satisfactory, since it was associated with fewer cases of wound dehiscence, infection and post-operative hernia. Many of the patients were elderly and were operated upon for malignant tumors. Stay sutures were used in only 35 per cent of the wounds closed by the catgut and silk technics.

### HERNIA

Follow-up results on 1039 of 1545 cases of hernia repair at the New York Hospital have been reported by Glenn.<sup>4</sup> The incidence of recurrences was as follows: indirect inguinal, 3 per cent; direct inguinal, 8.1 per cent; recurrent inguinal, 14.7 per cent; femoral, 8.5 per cent; umbilical, 11.8 per cent; epigastric, 9 per cent; and postoperative ventral, 12 per cent. Fine silk sutures were generally used. The cord was transplanted in 188 and not transplanted in 610 cases. There were 3 deaths in the series. Glenn believes that fascial repair would not have given better results but apparently bases this opinion on the experience of others.

Garner<sup>5</sup> analyzes the results of 2643 hernia repairs. In primary cases, catgut to Poupart's ligament gave 10 per cent recurrences and silk 7 per cent, whereas silk to Cooper's ligament resulted in only 3.4 per cent recurrences. In recurrent cases the use of Cooper's ligament gave poorer results with silk repair than those in which Poupart's ligament alone was used. The results with Galie repairs were better than those with McArthur's technic.

Gaston<sup>6</sup> and Christopher and Penna<sup>7</sup> have had favorable results with the McArthur fascial repair of inguinal hernia. Both use reinforcement with interrupted fine silk or cotton sutures. Gaston divided the cord and removed the testicle in 11 out of 201 repairs. His recurrence rate was 1.7 per cent. Christopher and Penna reported 3.1 per cent recurrences. An extensive experience with the combination of the McArthur and the Halsted I technic in the repair of primary inguinal hernia at the Massachusetts General Hospital inspires confidence in this method.

Dennis and Varco<sup>8</sup> describe an excellent approach to strangulated femoral hernia. The sac is exposed through a vertical incision from the crease of the groin distalward. If the appearance of the sac wall gives the impression that gangrenous bowel is present, the sac is not opened. An oblique incision is then made 2 cm. above and parallel to the inguinal ligament, and the two incisions are joined in a T shape. The abdomen is opened, and the caught loop of bowel is divided between four clamps. The inguinal ligament is then cut across near its pubic attachment. The portion of the ligament forming the fibrous ring around the neck of the sac is left *in situ* as the remainder of the proximal ligament is freed. The entire sac with its contents is then gently removed, and an end-to-end anastomosis of the intestine is carried out. Repair of the defect

including the detached inguinal ligament, is effected with fine silk sutures. Ten cases are cited with 1 death from ruptured aortic aneurysm and 1 from cardiac decompensation. The majority of the wounds followed revealed no evidence of weakness or recurrent hernia.

Williams<sup>9</sup> makes a good appeal for the use of the Laroque abdominal approach for the repair of sliding hernia. The abdomen is opened through a McBurney-like incision within the usual long oblique inguinal wound. This allows adequate exposure for the reduction of the hernia and the suture of the stretched retroperitoneal colonic mesentery. This method may be more adaptable than the combined inguinal and abdominal approach advocated by Graham.<sup>10</sup>

Cases of herniation through the foramen of Winslow are reported by Gillis<sup>11</sup> and by Hamilton and Hardy.<sup>12</sup> Both patients were men and were admitted to the hospital with sharp onset of pain, of a severe and continuous nature, with vomiting. A pre-operative diagnosis of perforated duodenal ulcer was made in each case. Jejunum of considerable length was reduced after finger dilatation of the foramen. The case of Hamilton and Hardy required the suture of a rent in the bowel produced during reduction. No resection was necessary in either case, and both patients recovered.

### RETROPERITONEAL TUMORS

A good review of the literature with a study of 95 cases of retroperitoneal tumors occurring in the University of Iowa Hospitals in a twenty-year period is given by Donnelly.<sup>13</sup> Eighty-one per cent were malignant in the following order: undifferentiated neoplasm, fibrosarcoma and sarcoma. Three of the benign tumors recurred — one metastasizing to the chest thirteen years after the primary operation. Of the 81 patients explored, 16 died. Thirty-five per cent were resected, with 30 per cent recurrences either local or metastatic. The author believes that 77 per cent of such tumors are radiosensitive and therefore advises excision in addition to postoperative radiation when possible and radiation alone in the nonresectable tumors.

### THE LIVER

Kisner<sup>14</sup> reports 3 cases of solitary liver abscess treated by drainage and penicillin, with recovery. He discusses the possibilities of aspiration of the abscess cavity with the installation of penicillin. It appears that drainage offers better opportunity for a successful outcome. The characteristic picture of this disorder is represented by chills and fever, rapid weight loss, nausea and vomiting with pain in the hepatic region.

Thorck<sup>15</sup> presents an excellent description of the six subphrenic spaces where abscesses are prone to develop. Three of the spaces are subhepatic, and three are above the liver and are delineated by the

anatomic structures of the region. The diagnosis of the space involved is best determined by the clinical signs and lateral roentgenograms. Approaches to each space are suggested.

Three cases of successful resection of hepatoma are reported by Duckett and Montgomery<sup>16</sup>. One case recurred after six months, but the other patients were well at the time of the report. Hemorrhage was controlled by the mattress-suture method of Pickrell and Clay<sup>17</sup>. These sutures are placed through the normal liver tissue in an interlocking manner before the section to be removed is severed. Fibrin foam was helpful in 1 case in controlling the bleeding. Digital compression of the portal vein and the hepatic artery is useful in obtaining accurate hemostasis.

### THE SPLEEN

Hodge and Wilson<sup>18</sup> discuss benign cavernous hemangioma of the spleen. Thirty-one cases are collected from the literature. The authors believe that angiosarcoma, angioendothelioma, angioblastoma, simple sinusoid ectasia and so forth are included in some reports as cavernous hemangioma and are obviously not benign. Many of the reported cases were incidentally found at autopsy and had apparently been asymptomatic. Others caused pain from the huge tumefaction, and some of the spleens had ruptured, causing massive intraperitoneal hemorrhage. Hemangioma appears to be a tumor comprised primarily of new blood vessels, the anlage of which is thought to arise from vascular disarrangements. One case is reported in a thirty-five-year-old Negress who was admitted to the hospital with a huge, painful left-upper-quadrant mass. At operation the spleen was removed after the aspiration of 12,000 cc of bloody fluid. The total weight of the tumor was 13,130 gm, and its greatest diameter was 28 cm. The authors believe that this is the largest benign cavernous hemangioma of the spleen thus far on record. The patient made a good recovery from the procedure.

### THE PANCREAS

Shallow and Wagner<sup>19</sup> report a probable case of traumatic pancreatitis in a boy of eight who fell from his bicycle, landing on the handle bars in such a way that direct trauma to the abdomen occurred. The serum amylase was very high on admission, and this was the chief criterion for the diagnosis. Conservative treatment with large doses of penicillin resulted in cure. The authors discuss the problem and conclude that from 2 to 4 per cent of all cases of pancreatitis are of traumatic origin.

Tumors of the islets of Langerhans are reviewed by Lopez-Kruger and Dockerty<sup>20</sup>. In 10,314 routine examinations of the pancreas, 44 tumors were revealed. In the careful study of 500 pancreases by the authors, 8 tumors of the islet cells were found. This leads them to the obvious conclusion that such

tumors are usually symptomless and that hypoglycemia is a rare manifestation. When hypoglycemic symptoms occur, however, an attempt at medical management is justified. If this fails, the tumor must be excised. The authors state that 50 to 60 per cent of the tumors causing symptoms can be found and removed at the first exploration. Since the tumors are often multiple and the majority of them inactive, repeated operations are frequently necessary to relieve the patient. Resection of the tail of the pancreas will remove 50 per cent of the tumors. The body of the organ contains 20 per cent, and the remainder are found in the head. Only 1 or 2 per cent have an extrapancreatic location. Surgeons must be prepared to carry out procedures ranging from shelling out an easily accessible tumor to total pancreatectomy in patients who fail to be relieved by less extensive resections.

Marble and McKittrick<sup>21</sup> report 6 cases of islet-cell tumor of the pancreas with hyperinsulinism. Five patients had benign adenomas, and all of these were relieved. One patient had a mixed-cell type of carcinoma, with metastases to the liver, and succumbed seven weeks after operation. The lesions were found in the head of the pancreas in 4 cases and in the body in 1, and the malignant lesion originated in the tail of that organ. The authors stress early diagnosis and operation to avoid permanent central-nervous-system damage from repeated attacks of hypoglycemia and in the hope of cure when the lesion is malignant.

Carcinoma of the islets of Langerhans with hyperinsulinism is discussed by Sanchez-Ubeda and Carr<sup>22</sup>. Twenty-three cases are collected from the literature, and the detailed report of a case of their own is given. This occurred in a forty-year-old man, with typical attacks of hypoglycemia, who was brought into the hospital in coma. Death resulted, and autopsy revealed a primary carcinoma of the pancreas, with evidence of islet-cell origin. Metastatic lesions in the liver were microscopically identical with those found in the pancreas.

Most surgeons will agree with Pearse<sup>23</sup> that standardization of the Whipple operation for pancreaticoduodenectomy is necessary. The principles involved are end-to-end anastomosis of the common bile duct to the jejunum, anastomosis of the pancreatic duct to the side of the jejunum, with reinforcement by suturing the capsule of the pancreas to the wall of the jejunum, and anastomosis of the end of the stomach to the side of the jejunum. This logical plan directs pancreatic and stomach contents away from the liver so that ascending cholangitis is less likely to occur. It is natural that in the formative years of the development of this operation many ingenious modifications have been produced. Now that the procedure is done by so many surgeons, the standardization of the principles involved should be more universally adopted, with rare variations.

## APPENDICITIS

Meyer et al.<sup>24</sup> have analyzed the records of 5543 cases of appendicitis treated at the Cook County Hospital, Chicago, from 1928 to 1944. The mortality rate had decreased from 7.6 to approximately 4.0 per cent largely owing to the following factors: the nonoperative treatment of acute appendiceal abscesses, the more consistent use of the McBurney incision, and the omission of drainage of the peritoneal cavity. The advent of intravenous therapy and gastric suction, blood transfusion and antibiotics is stressed in order of common usage to account for the reduction in mortality.

Shullinger<sup>25</sup> has studied the results of the improvement in methods of treatment of acute appendicitis over a period of years at the Presbyterian Hospital in New York City. The mortality from 1916 to 1945 was 3.55 per cent. The last five-year average was 1.37 per cent, whereas for the year 1945 only, the rate was 0.43 per cent. Shullinger calls attention to the fact that local peritonitis has responded less favorably to modern methods of treatment than other complications of the disease.

McClure<sup>26</sup> reported that there had been no fatalities in 1089 consecutive cases of acute appendicitis in the past four years treated in the Henry Ford Hospital, Detroit. There had been a steady reduction in mortality from 0.92 per cent ten years ago up to the present time.

Hoerr<sup>27</sup> has evaluated progress in the treatment of acute appendicitis at the Peter Bent Brigham Hospital, Boston, for each five-year period from 1913 to 1945. There was little change for the better until the last period of his study, which comprised 382 cases with only 1 death. He concludes that sulfonamides acting systemically, gastric suction, the McBurney incision and the omission of drains are, in that order, responsible for the improved results.

Hurwitt<sup>28</sup> calls attention to the onset of acute appendicitis in patients undergoing treatment for other diseases. Ten such cases are collected from the records of the Mt. Sinai Hospital in New York City. He stresses the difficulty in making the diagnosis in such patients, owing to the concentration on the more obvious pathologic process for which the patient is being treated.

Mucocele of the appendix is discussed by Kirby,<sup>29</sup> who reports such a case in a forty-one-year-old woman who was admitted to the hospital with a diagnosis of acute appendicitis. The mucocele removed was 8.5 cm long and 5.5 cm in circumference. Kirby was able to collect 250 cases of this disease from the literature. The correct diagnosis is seldom made preoperatively and is usually made at operation for appendicitis, exploratory laparotomy or right hemicolectomy, or is an incidental autopsy finding. The results are good after appendectomy.

## THE GALL BLADDER AND BILE DUCTS

Congenital absence of the gall bladder is discussed by Latimer et al.<sup>30</sup> Seventy-one cases are collected from the literature. Thirty-eight of these were post-mortem findings, and 34 were discovered at operation. The authors report 3 cases from the Wesley Memorial Hospital, Chicago. They found that cholangiography was a reliable method of ruling out intrahepatic gall bladder.

Mahoney<sup>31</sup> reports 18 cases of cholecystoduodenocolic membranes encountered at the Strong Memorial Hospital, Rochester, New York. Most of these congenital bands have no pathologic significance, but a few may cause pain simulating cholecystitis or duodenal ulcer, or both. Some patients are relieved of symptoms after the division of the membranes. Mahoney believes that the reports in the literature regarding the incidence of 15 to 30 per cent are too high and that too much emphasis has been placed on their importance.

Daseler et al.<sup>32</sup> have studied the variations in the cystic artery in 500 specimens, finding twelve distinct patterns. This important anatomic contribution should be constantly borne in mind by surgeons. A good many of the catastrophes occurring during cholecystectomy are the result of unrecognized anomalies in this region. Abnormal distribution of the blood supply to the gall bladder and the liver is so commonly seen that too much emphasis cannot be placed on its surgical significance.

In two articles, Zaslow and his associates<sup>33, 34</sup> have reported the concentration of penicillin and streptomycin in the human gall bladder and the common hepatic duct. If the cystic duct is obstructed, the antibiotics will not reach the gall bladder. If the common duct is obstructed at the papilla of Vater, there is also lack of concentration of these agents in the hepatic ducts. In the absence of obstruction, the concentration was satisfactory in both series with the usual parenteral doses of the drugs.

Glenn<sup>35</sup> collected 17 cases of acute cholecystitis occurring in patients under treatment for other diseases in the New York Hospital in a period of fourteen years. He stresses the importance of an early diagnosis and operation in these cases because of the danger of gangrene and perforation. Symptoms are often attributed to nonsurgical complications or to conditions related to the original pathologic process. He considers it sound practice to study the condition of the gall bladder in all patients beyond the age of fifty who are about to undergo surgical procedures.

McGowan et al.<sup>36</sup> advocate a modified T tube for common-hepatic-duct drainage. A balloon is attached to the side of the long arm of the tube in such a manner as to prevent distortion of the common duct while the T tube is in place. By measuring, in millimeters of water, the amount of pressure within the duct that produces pain the authors be-

lieve that they can determine the optimum time for removal of the tube

Varco<sup>37</sup> has made a notable contribution in the treatment of pruritis in patients with certain chronic liver disorders. A small T tube is placed in the common hepatic duct as a permanent safety valve. Bile is allowed to drain to the outside for a few hours daily. Each patient may work out the amount of drainage necessary to maintain comfort. Varco believes that the itching is due to the concentration of bile salts in the blood serum and points out that 90 per cent of the bile salts excreted by the liver each twenty-four hours is reabsorbed from the intestine to be recirculated through the liver. Cholecystostomy was not effective in relieving these patients.

Incomplete removal of the cystic duct is thought by Hicken and his co-workers<sup>38</sup> to result in continued symptoms in cholecystectomized patients. They stress careful dissection of the cystic duct to near its junction with the common hepatic duct. It is important to leave no small stones or debris in the cystic duct. These authors consider more common use of cholangiography on the operating table to be of value in determining the length of the retained cystic duct and whether or not it is clear.

Womack and Crider<sup>39</sup> believe that from 5 to 20 per cent of patients continue to have symptoms after cholecystectomy. Reoperation on such patients revealed neuromas of the amputation type in 6 cases. Anatomic studies of the nerve supply to the region were made, and the authors conclude that careful denervation of the cystic duct should be accomplished in every cholecystectomy. The neuromas may be produced by scar tissue or trauma if the nerves are included in the tie with the cystic duct or with the cystic artery.

Lagerlöf<sup>40</sup> has relieved 14 patients of biliary dyskinesia by choledochal denervation. One patient was not improved by the same operation. He stresses the section of the nerves in the hepaticoduodenal ligament. After the operation, patients were given morphine and secretin simultaneously, and elevation in the serum amylase and bilirubin was less than that before operation with the same drugs. Lagerlöf believes that this test shows that the action of the sphincter mechanism of Oddi has been lessened by the procedure.

Grimson et al<sup>41</sup> have removed the celiac and supramesenteric ganglions in 4 patients with biliary dyskinesia. Three of the patients were relieved of their symptoms by this operation. A high subcostal incision is used, and the ganglions are exposed by division of the gastrohepatic omentum.

Smithwick and Chapman<sup>42</sup> have made studies in about 12 patients with biliary dyskinesia before and after right splanchnicectomy. Some of the patients have also had left lumbodorsal splanchnic resection. More than half of these patients have been relieved of their symptoms.

Smithwick<sup>43</sup> has also been successful in relieving severe pain in a patient with calcareous deposits in

the head of the pancreas by right lumbodorsal splanchnicectomy. This patient was rapidly becoming a morphine addict, and her pain was in every way similar to that of patients with biliary dyskinesia.

Petrov and Krotkina<sup>44</sup> have experimented with the production of carcinoma of the gall bladder in guinea pigs. Glass tubes, some of which contained a small amount of radium, were introduced into the gall bladders of 100 animals. Fifty-one of these lived over fourteen months, and of those 5 developed carcinoma of the gall bladder. Two were in the radium-tube experiments, but 3 were in the sterile-tube cases meant to be used as controls. It required from fourteen to thirty-nine months for these animals to develop carcinoma, 4 of them had metastases to other organs. The authors believe this to be supportive evidence that foreign bodies, such as stones within the gall bladder, predispose to the development of carcinoma of that organ.

Barnes and Zarr<sup>45</sup> report a case of papillary adenocarcinoma of the common hepatic duct localized above the entrance of the cystic duct. The lesion was excised, and a subtotal cholecystectomy was done. The remaining lower segment of the gall bladder was anastomosed end to end with the dilated but normal proximal portion of the common duct, a satisfactory re-establishment of continuity being thus obtained.

### THE STOMACH

Ransom<sup>46</sup> gives the statistical data on 1356 patients with gastric ulcer treated in the University of Michigan Hospital in a twenty-year period. Two hundred and forty-six patients were treated surgically, of whom 20 had acute perforation. One hundred and eighty-eight had gastric resections, and 38 had palliative procedures. The indications for operation were as follows: intractable to medical therapy, 36.7 per cent, possible carcinoma, 29.8 per cent, obstruction, 21.8 per cent, penetrating ulcer, 5.3 per cent, hemorrhage, 4.8 per cent, and question of perforation, 1.6 per cent. Ten and one tenth per cent, thought to be benign, proved on pathologic examination to be malignant, and 40 per cent of these were apparently cured. The over-all operative mortality was 7.9 per cent, most of the deaths occurring prior to 1936. Ninety-two per cent of the benign ulcers treated surgically had a satisfactory result. Four patients developed anastomotic ulcer, 3 of whom definitely had part of the pyloric antrum retained at the original resection, the other case was questionable in this respect.

O'Donoghue and Jacobs<sup>47</sup> review primary lymphosarcoma of the stomach. They cite Taylor's<sup>48</sup> report in 1939 of 152 cases collected from the literature with 5 from the Presbyterian Hospital in New York City. One hundred new cases are collected from the literature between March, 1937, and January, 1946. They add a patient of their own who was alive and well five and a half years after subtotal gastrectomy.

Radical surgery followed by radiation appears to give the best results in such cases

Coexistent duodenal ulcer and gastric cancer is discussed by Fischer et al<sup>49</sup> from the Mayo Clinic. Between 1911 and 1945, 45,000 patients with duodenal ulcer were seen. Forty-eight cases of gastric cancer were found in this group. This amounted to 1 case in 938, or 0.1 per cent. The acidity of the gastric contents was valueless in making the diagnosis of cancer in these patients, although 2 of them appeared with healed duodenal ulcer and achlorhydria. Nearly all the patients had changed or increased symptoms. Four of them had been previously operated on for duodenal ulcer. The average duration of stomach symptoms in the entire group was eleven years and four months. Results apparently better than those observed in the usual cases of gastric cancer were attributed to the fact that these patients were stomach conscious.

Boyce<sup>50</sup> gives credit to Laennec (1823) for the first report of acute perforation in gastric cancer. It is apparent that this common complication is rarely reported in the literature, since only 230 such cases have appeared. Thirty-six cases are included in Boyce's study; 3 patients were subjected to gastric resection, with 2 survivors. He agrees with Bigard and Overmiller<sup>51</sup> that this is the procedure of choice.

Hartnett<sup>52</sup> has made a collective study of 1405 cases of cancer of the stomach from the London hospitals for the years 1938 and 1939. Forty-nine and two tenths per cent were operated on, but only 17.3 per cent had resections. The operative mortality for patients treated radically was 32.9 per cent. Excluding the operative deaths, the five-year survival averaged 23.1 per cent. The average life of all patients, whether treated or not, was 27.4 per cent of normal, those resected before nodal involvement averaged 60 per cent, whereas those resected after nodal spread averaged 40 per cent of normal—a five-year life expectancy.

Abrahamson and Hinton<sup>53</sup> compare two series of cases of carcinoma of the stomach treated at Bellevue Hospital, New York City. In the first group, there were 2.2 per cent of possible cures, and in the second or later group, there were 5 per cent apparently cured. They stress the lack of progress in making an early diagnosis. They found little evidence to support the theory that benign ulcers change to cancer.

State et al<sup>54</sup> give a statistical review on 586 patients with cancer of the stomach seen in the University of Minnesota Hospitals in a ten-year period. Seventy-six and three tenths per cent were operated on, and 52.2 per cent had a resection. There were 276 partial and 31 total gastrectomies in the group. The operative mortality was 15.2 per cent in the partial and 30 per cent in the total resections, averaging 16.6 for the whole. This has been reduced from 25 per cent in 1936 to 4.9 per cent in 1945. Six and six tenths per cent of patients having resection

lived five years, this represents 21.5 per cent of those surviving the operation.

Pack, in discussing this paper, gave the figures on cancer of the stomach collected by McNeer at the Memorial Hospital in New York City. Six hundred and eighty-three patients were seen, and 79 per cent operated on. Thirty-five per cent had resections. The operative mortality was 12.2 per cent in the partial and 30 per cent in the total resections. There was a 34.7 per cent five-year salvage in patients surviving resection.

These figures coincide fairly well with those collected from the Massachusetts General Hospital by Welch and Allen<sup>55</sup>. The resectability is now about 50 per cent of all cases seen. The operative mortality has been reduced to 3 per cent for partial, but is still about 30 per cent for total gastrectomy. The transthoracic approach to tumors involving the cardia of the stomach, with extension to the lower esophagus, has increased the number of resections. The net five-year salvage has been raised from 5 to 7 per cent of all patients admitted. A more radical attitude in the treatment of gastric ulcer, because it is often impossible to distinguish a benign from a malignant lesion, will improve the cure rate. It was disappointing to find that patients do not appear for treatment earlier now than they formerly did.

Longmire<sup>56</sup> believes that total gastrectomy is the operation of choice in gastric cancer. He reports 20 cases treated in this manner, with 2 deaths. Seven patients were alive for more than a year and were eating well. Two patients had died of malnutrition after discharge from the hospital. He believes that such patients can be kept well on proper diet and so forth, and that those who have no appetite must be taught to eat regularly in adequate amounts.

It is quite obvious that the operative mortality for total gastrectomy can be reduced to a low level if all cases with cancer of the stomach are so treated. It is doubtful, however, that such a radical attitude is logical. It is admitted that a partial resection in many cases is inadequate. Recurrent disease, however, seldom appears in the remaining stomach segment. If one can obtain a good nodal dissection and transection of the stomach through normal tissue, the risk is reduced, and the patient is less apt to have nutritional difficulties and will probably have just as good a chance of cure as if the whole stomach had been removed.

Ransom<sup>57</sup> reports 60 cases of total gastrectomy at the University of Michigan Hospital between 1937 and 1946. Fifty-three patients had cancer, 4 benign ulcer mistaken for cancer, 2 lymphosarcoma, and 1 neurofibroma. Forty-eight patients survived the operation—a mortality of 23.3 per cent. Those who died of metastasis averaged ten and a half months of life. One patient was alive and well for seven years and eleven months, 1 for six years and one month, 1 for four years and five months, and 2 for one year and six months. Six patients—2

with recurrent disease — were alive from one to eight months

Gray, in a discussion of Ransom's paper, reported 124 cases of total gastrectomy at the Mayo Clinic with an over-all mortality of 40.3 per cent. This had been reduced to 16.6 per cent in the most recent 24 cases.

Smith<sup>58</sup> gives some interesting data on 89 patients subject to total gastrectomy at the Lahey Clinic. The mortality for the entire series was 29.1 per cent, which had been reduced to 16.3 per cent in the last 43 cases. He gives the life expectancy as follows: 50 per cent of patients will live twelve months, 28 to 38 per cent eighteen months, 16 to 29 per cent twenty-four months, and 9 to 21 per cent three or more years. Twelve patients lived three or more years. One was alive eight years and five months after a total resection for leiomyosarcoma, 1 for seven years and one month (having had lymphosarcoma), and 1 for five years and four months whose diagnosis was carcinoma simplex.

Lefèvre<sup>59</sup> and Orr<sup>60</sup> have reported modifications in esophagojejunostomy. Both transect the jejunum. Lefèvre closes both ends and does an end-to-side anastomosis after attaching the distal limb to the diaphragm posteriorly, then the proximal limb is sutured to the diaphragm in front of the esophagus and to the distal limb to protect the anastomosis. This is followed by a large stoma between the two jejunal limbs. Orr uses the distal closed limb of jejunum for an end-to-side hook-up with the esophagus and then implants the proximal jejunum into the distal limb at a low level after the method of Roux.

(To be concluded)

### CASE 34101

#### PRESENTATION OF CASE

A twenty-one-year-old nulliparous housewife entered the hospital complaining of dyspnea of seven months' duration.

The patient was reported to have been a "blue baby" at birth and remained blue for several weeks. From then until the age of two years she was supposedly of normal coloring. At that time she had a spiking febrile episode without other symptoms, which was diagnosed as rheumatic fever. Thereafter she led a restricted existence and was never able to play with other children because of marked exertional dyspnea and cyanosis. During the ensuing fifteen years she had always had orthopnea requiring two pillows at night, frequent bouts of variable muscle and joint pains and seemingly unassociated episodes of spiking fever. Clubbing of the fingertips had been noted since an early age. During the past four years she had been followed in the Out Patient Department, where it was noted that she had a Grade IV systolic murmur, loudest in the second interspace to the left of the sternum. One year before admission she had some increased dyspnea and was thought to have slight neurocirculatory asthenia. Seven months before entry, following an emotional episode, she neglected her health and had another febrile episode, with a definite increase of cyanosis. She was hospitalized during a period of severe exertional dyspnea, the orthopnea requiring an increase from two to four pillows, hand and ankle edema, increased abdominal girth and epigastric pressure symptoms on effort. Two and a half months before entry she had a single episode of hemoptysis and hematemesis, followed by black stools for two days. Since that time she had been symptomatically stable, with less cyanosis, pain and edema but with fifteen brief episodes of shaking chills and frequent night sweats in the two weeks previous to entry.

Physical examination revealed a thin, dyspneic woman with marked cyanosis and clubbing of the fingertips. There was no edema or petechiae. The heart was enlarged, and the pulmonic second sound

was louder than the aortic second sound, there were a systolic thrill at the apex and a Grade IV precordial systolic murmur, a continuous low-pitched pulmonic murmur and a Grade II diastolic blow along the upper left border of dullness.

The temperature was 100°F, the pulse 108, and the respirations 26.

Examination of the blood revealed a red-cell count of 9,300,000, a hematocrit of 76, a hemoglobin of 24 gm per 100 cc and a white-cell count of 4500, with a normal differential count on several occasions. Urinalysis disclosed a specific gravity of 1.010 and a +++ test for albumin. The nonprotein nitrogen was 35 mg, the total serum protein 6.5 gm per 100 cc, with an albumin-globulin ratio of 1.64, and the chloride 105 milliequiv per liter.

X-ray examination showed the heart to be slightly diffusely enlarged, with a cardiothoracic ratio of 13/25, left auricular enlargement and some evidence of pulmonary fibrosis were demonstrated. The edematization rate was 0 mm per hour. The venous pressure was equivalent to 160 mm of water, and the circulation time sixteen to twenty seconds (arm to tongue). The vital capacity was 1.7 liter. Daily blood cultures failed to grow any organism either aerobically or anaerobically.

The electrocardiogram showed an enormous P wave in Lead 2, a very prominent P wave in Lead 3 and a PR interval of 0.18 second. Right-axis deviation was moderate. The T waves were low and upright in Lead 3 and upright in Leads 1 and 2 and CF<sub>1</sub>, CF<sub>2</sub> and CF<sub>3</sub>.

The hospital course, which lasted for three weeks, was remarkable only in that the daily temperature spiked to 100°F by rectum and to 102°F on the last three days. The dyspnea, orthopnea and cyanosis improved on bed rest for a while but became more marked in the last few days and were associated with some precordial-pressure symptoms, increased weakness and distress. The pulse rose to 120, the systolic blood pressure was maintained around 90 mm, with an indefinite diastolic level. Physical findings did not change appreciably, the lungs remained clear, and no peripheral edema appeared. The patient was placed in an oxygen tent on the twentieth hospital day. Penicillin therapy was begun. On the twenty-first day venesection of 500 cc of blood was done, with temporary relief of symptoms, but she suddenly stopped breathing and died that night.

#### DIFFERENTIAL DIAGNOSIS

DR. PAUL D. WHITE: I am glad to have been given this case, because I am sure that I shall learn something from it. I have never seen a case like this to follow through, although Dr. Mallory tells me that I did see this very patient some time ago when she was still living. I have, however, forgotten all about her. I am sure that I was as puzzled then regarding the actual answer as I am now.

One rarely sees a spiking febrile episode due to rheumatic fever under the age of three or four. This occurred in the case under discussion at the age of slightly over two years, and we must have some reservation about that episode. I do not know the cause. From the age of two the patient was very short of breath and cyanotic as she had been at birth. That restricted her activities very greatly. With the muscle and joint pains and fever, although they are not necessarily associated, we must think seriously of rheumatic fever, which, however, is a very rare complication of the *maladie bleue* in the first few years of life. The clubbing of the fingers and cyanosis coming on at birth make one think strongly, of course, of the tetralogy of Fallot.

The Grade IV systolic murmur is in keeping with the tetralogy of Fallot in which there is pulmonary stenosis. Sometimes there is a loud murmur and sometimes a relatively slight one, and rarely there is no murmur. So far the history fits the ordinary tetralogy of Fallot.

The latest febrile episode seven months before entry again makes one wonder about rheumatic fever or pulmonary infection.

The ankle edema and increased abdominal girth were probably due to venous congestion and engorgement of the liver on effort, which are evidence of total or right-sided heart failure.

The hematemesis may have come from swallowed blood. The hemoptysis is more important and must be ascribed to pulmonary infection, infarction or congestion, such as one sometimes encounters with mitral stenosis.

The shaking chill and the frequent night sweats are something else again. Rheumatic fever generally does not cause such symptoms, they strongly suggest a superimposition of bacterial endocarditis, in the absence of more definite evidence of pulmonary or other infection.

The marked cyanosis and clubbing of the fingertips on physical examination still remind one of the tetralogy of Fallot.

A continuous murmur if actually present must mean an arteriovenous shunt, almost certainly a patent ductus arteriosus. One may be fooled, however, by a continuous murmur at the base of the heart, which can be transmitted from the neck veins. The so-called venous hum is best heard in a child, this patient was no longer a child. The venous hum may be confused with the murmur of a patent ductus arteriosus. There are really no other conditions to be seriously considered in that region that give a continuous murmur.

Was the diastolic blow due to aortic or pulmonary regurgitation? We have seen it in the tetralogy of Fallot in 2 cases, in 1 with pulmonary stenosis and regurgitation, and in 1 with aortic regurgitation.

It is, however, very rare. The other findings — that is, the loud pulmonic second sound, the systolic thrill and the murmur — are not consistent with a diagnosis of uncomplicated tetralogy of Fallot. They are important clues and begin to lead us away from the ordinary uncomplicated tetralogy of Fallot.

The blood findings are characteristic of the morbus caeruleus or *maladie bleue*, of which the tetralogy of Fallot is the most common example. A good many other cyanotic congenital heart conditions, however, cause a polycythemia.

The albuminuria may be ascribed to renal congestion. The patient had congestive failure. An independent renal difficulty is possible, but less likely.

The left auricular enlargement and the pulmonary fibrosis demonstrated by x-ray examination are most extraordinary findings. Unfortunately the films have been lost. I wanted to make sure that there was really a large left auricle and not a right auricle, or some other part of the heart. That must be an important clue. Enlargement of the left auricle is not seen in the tetralogy of Fallot.

The pulmonary fibrosis is the second important clue. I wonder if there was any question between pulmonary fibrosis and pulmonary vascular congestion.

DR STANLEY M. WYMAN: I read the description, and the fibrosis was not so definitely stated. The observer believed that it might be congestion of the vascular shadows. We did think that there was left auricular enlargement, however.

DR WHITE: That was quite definite, evidently.

DR ISAAC TAYLOR: Our opinion was that the pulmonary findings on x-ray examination were mostly vascular.

DR WHITE: We do not see that in the tetralogy of Fallot, in which the lungs are undersupplied with blood and the left auricle is not large. The x-ray findings and the auscultatory data are very important clues.

How many cultures were taken?

DR LEWIS K. DAHL: I would say a minimum of twenty-one. They were all negative.

DR WHITE: The electrocardiogram showed an enormous P wave in Lead 2. It must have been one of the largest P waves ever seen. We see large P waves in cases of the tetralogy of Fallot and of auricular septal defect, but I do not believe that we have ever called them enormous. The P waves were also large in Lead 3. Right-axis deviation was moderate. That is important and one of the many clues, because with such prominent P waves as these associated with the tetralogy of Fallot or an auricular septal defect marked right-axis deviation should have been present.

Penicillin was finally begun despite the fact that no positive cultures were obtained. There had been a considerable delay, but at last — in desperation — penicillin was apparently used. Whether it

was begun because of the suspicion of subacute bacterial endocarditis or endarteritis or because an infection of uncertain cause was suspected, I do not know.

This is obviously a puzzling case. There are three important questions. In the first place, was this congenital heart disease with complications, or was it early rheumatic heart disease that might be traced back to birth or fetal life, if such a case ever occurs? I do not know that I have encountered or ever heard of a case of rheumatic heart disease present at birth. Was it rheumatic superimposed on congenital heart disease, or was it something entirely different?

In the second place, what structural defects were present to explain all the findings? Were there more than one? Do we have to make more than one diagnosis?

And thirdly, what was responsible for the febrile episodes and final fever and death? I cannot answer these questions with assurance but in attempting to answer them, I shall give my own opinions, which I am sure can be readily replaced by others.

In the first place, I favor congenital heart disease with complicating infection, which need not be rheumatic although the combination is very appealing because of the recurrence of the febrile episodes. I doubt the possibility of rheumatic heart disease alone without any congenital defects. Secondly, it seems to me that we must make one or the other of the diagnoses—congenital or rheumatic or the two together. I cannot imagine other types of heart disease in this case. Despite the early cyanosis and clubbing there are objections to the diagnosis, not only of the commonest cause of such signs—namely, the tetralogy of Fallot—but also of certain other defects behind a *morbus caeruleus*, such as Eisenmenger's complex, transposition of the great vessels, a single ventricle and tricuspid atresia, in the last of which left-axis deviation is the rule in the cases that are on record, instead of right-axis deviation such as that recorded here, tricuspid atresia is a clinical syndrome that now can be diagnosed as a result of Helen Taussig's work.<sup>1</sup>

Accentuation of the pulmonic second sound, the systolic thrill at the cardiac apex, the left auricular enlargement and the pulmonary fibrosis by x-ray study, as well as the enormous P waves, with only moderate right-axis deviation, in the electrocardiogram, are all contrary to what we expect to find in the tetralogy of Fallot, and most of them are contrary to what we expect to find in the other four less common types of the *morbus caeruleus* mentioned above. These findings by auscultation, x-ray examination and electrocardiogram seem to be most important clues. If we can fit them together they certainly point to mitral-valve deformity—probably stenosis and regurgitation. I do not remember having seen a patient with

congenital mitral stenosis, but I know that such a condition exists. In Maude Abbott's<sup>2</sup> 1000 autopsied cases of congenital heart disease there were 6 with a primary diagnosis of mitral stenosis. Equally rare or probably much rarer is rheumatic mitral stenosis in infancy, unless one can attribute congenital mitral stenosis to rheumatic infection in the fetus, with which I am not familiar. The continuous pulmonary murmur points strongly to a patent ductus arteriosus as a complication of whatever else this patient had. That is the commonest complication of congenital mitral stenosis in Abbott's cases, but I may be stretching a point. If we diagnose mitral stenosis, we can readily explain also the early dyspnea, the hemoptysis, and the "pulmonary fibrosis," which might be based on chronic pulmonary stasis. But how can we explain the high degree of cyanosis, the clubbing and the polycythemia? Severe chronic pulmonary stasis from birth might conceivably do that. Or is it not possible that a patent ductus arteriosus alone allowed a right-to-left shunt of venous blood directly into the aorta as the result of a high pressure in the pulmonary circulation? There was, to be sure, no mitral diastolic murmur, but cases of congenital mitral stenosis are already on record with only an apical systolic murmur.

Finally, was there rheumatism too, off and on, to explain the fever? I do not know. Or was it all rheumatism at an extremely early age? Or was there infection of other sort, recurrently, or quite possibly pulmonary infarction? Again, I do not know, but there was no proof thereof. Was there subacute bacterial infection involving the ductus or the pulmonary valve or even the mitral valve? That is also possible, but I find no proof. At the end penicillin was started quite likely with that possibility in mind.

Is it possible that an arteriovenous fistula in the left lung was responsible for the continuous pulmonary murmur instead of a patent ductus? Such a cause is very unlikely. The early diastolic murmur along the left sternal border could have been due to either slight aortic regurgitation (rheumatic) or relative pulmonary insufficiency secondary to the pulmonary hypertension, which is more likely, or to a remote primary lung disease.

In summary, my diagnoses are a congenital abnormality, with the *morbus caeruleus*, and with mitral-valve disease (stenosis), patent ductus arteriosus, pulmonary congestion, right-sided heart failure and recurrent infection (? rheumatic), with terminal subacute bacterial endocarditis or endarteritis or possibly rheumatic myocarditis.

DR TRACY B. MALLORY: Will you tell us what opinion was held on the ward, Dr Taylor?

DR TAYLOR: The only comment that I might make is in relation to the last few days of the patient's illness. She did not seem very ill throughout most of the hospital stay, except for an irregular

temperature, going up to 100 and 100.5°F daily until the last three days, when she became intensely cyanotic, and that progressed until her demise. With the progression of the cyanosis she became more and more lethargic. It was this change in her condition that prompted the giving of penicillin without bacteriologic diagnosis of endocarditis. Perhaps we delayed too long.

DR WHITE: It is still conceivable that there could be a shunt between the right ventricle and the aorta directly without supposing a reversal of flow.

DR BERTRAND WELLS: I should like to add two points. One was that the veins in the neck had large pulsations. These consisted of A waves and were almost synchronous with the abnormally large P waves of the electrocardiograms. The other point is that inside the apex there was a presystolic murmur. This was between the apex and the left sternal border, and it was doubtful whether this was in the mitral or the tricuspid area. I think that further phonocardiograms might have clarified this point.

DR WHITE: We might have to shift the stenosis from the mitral to the tricuspid valve on the basis of those findings (or add the two together).

#### CLINICAL DIAGNOSES

Subacute bacterial endocarditis, organism unknown

Congenital heart disease, type unknown

#### DR WHITE'S DIAGNOSES

Congenital heart disease morbus caeruleus

Mitral-valve disease (stenosis)

Patent ductus arteriosus

Pulmonary congestion

Right-sided heart failure

Recurrent infection (? rheumatic), with terminal subacute bacterial endocarditis, endarteritis or possibly rheumatic myocarditis

#### ANATOMICAL DIAGNOSES

*Congenital heart disease tetralogy of Fallot*

*Acute and chronic rheumatic endocarditis, with stenosis involving all valves*

#### PATHOLOGICAL DISCUSSION

DR MALLORY: The heart was one of the most remarkable that I have seen. There was congenital heart disease, which I thought was basically a tetralogy of Fallot: the pulmonary valve was stenotic, the interventricular septum showed a large defect at the base, there was dextraposition of the aorta, the right ventricle was markedly hypertrophied, and the left ventricle was small. The ductus arteriosus was a prominent fibrosed cord with dimpling at each end but not patent in its mid-portion. We thought perhaps it had become recently occluded within a period of a few months. In addition, all the valves of the heart were ab-

normal. There was a marked tricuspid stenosis, a pin-point mitral stenosis and a slight but significant aortic stenosis, with possibly a little aortic regurgitation. Vegetations were found on all valves. The vegetations were small, firm and characteristic of fresh rheumatic rather than bacterial vegetations.

The post-mortem cultures were sterile as were those taken during life. Microscopical examination showed almost no inflammatory reaction, although a trace of palisading was present at the base of two of the vegetations.

DR WHITE: Were there any Aschoff nodules in the myocardium?

DR MALLORY: None in eight blocks of tissue that were sectioned. A few minute fibrous scars were present, but they were not characteristic.

DR WHITE: Do you suppose that the rheumatic heart disease was superimposed on the tetralogy of Fallot?

DR MALLORY: Yes, I think that there is no other explanation of the picture. I do not believe that this many valves could have been congenitally stenotic.

DR WHITE: I do not believe so either.

DR TAYLOR: At autopsy I believe that an ante-mortem thrombus was found in the mitral valve.

DR MALLORY: There was a thrombus in the left auricle immediately above the mitral valve.

#### CASE 34102

#### PRESENTATION OF CASE

A seventy-one-year-old woman, a retired clerical worker, entered the hospital with the chief complaint of abdominal pain and vomiting.

Six weeks before admission she was suddenly seized with severe abdominal pain to the left of the umbilicus and vomited almost at once. She was taken by ambulance to another hospital, where on conservative therapy the symptoms subsided and she was discharged ten days later. About once a week thereafter she had an attack of crampy, non-radiating pain to the left of the umbilicus that was accompanied by vomiting. The attacks lasted several hours. The present episode, which had begun eighteen hours before entry, started with pain, followed by vomiting, twelve hours before admission. The patient had not had a bowel movement for two days but had passed a little gas twelve hours before admission. On two occasions in the month prior to admission tarry stools were noted. For many years she had been slightly constipated, and there had been no recent change. There was no history of

intolerance to fatty foods, jaundice, urinary symptoms or previous gastrointestinal symptoms.

The past history was noncontributory except for a "shock" three years previously, resulting in a transitory hemiplegia. The patient had three children, one of whom had died of cancer at the age of forty-four.

Physical examination revealed a mildly dehydrated woman in moderately acute distress due to pain and vomiting. The heart and lungs were not remarkable. Marked tenderness was present to the left and slightly above the umbilicus, with referred rebound tenderness to this area. A mass was felt by one observer in this area, but its presence was not confirmed by others. Peristalsis was normal. Pelvic and rectal examinations were negative.

The temperature was 100°F, the pulse 88, and the respirations 20. The blood pressure was 170 systolic, 100 diastolic.

The urine gave a ++ test for albumin but was otherwise normal. Examination of the blood disclosed a white-cell count of 15,300 and a hemoglobin of 12 gm per 100 cc. A guaiac test on the stools was ++, but three subsequent specimens were guaiac negative. Twelve hours after admission the serum amylase was 23 units, the protein 5.9 gm, and the nonprotein nitrogen 25 mg per 100 cc, and the chloride 104 milliequiv per liter. The serum van den Berg was normal. A plain abdominal film showed several loops of moderately dilated small bowel and gas in a normal large bowel.

Conservative therapy was decided upon, and a Miller-Abbott tube was passed. The patient improved, the small bowel returned to normal size, and several days later a negative barium enema was done. Following this barium was given through the Miller-Abbott tube, which showed a 2.5-cm narrowing of the bowel distal to the tube. The lumen of the narrow portion was smooth and 4 mm in diameter. Two cholecystograms subsequent to removal of the Miller-Abbott tube showed no filling of the gall bladder.

Operation was planned for the fourteenth hospital day. On that morning the patient developed a temperature of 100.4°F, the highest since admission, and generalized crampy abdominal pain without vomiting. There was generalized abdominal tenderness, most marked in the right upper and lower quadrants. Peristalsis was normal and the white-cell count reached 30,000 (it had been 9000 three days before). Despite this, operation was performed as scheduled.

#### DIFFERENTIAL DIAGNOSIS

DR. S. PETER SARRIS: This is the case of a seventy-one-year-old woman with a relatively short history of abdominal pain. Six weeks before admission she had recurrent attacks of severe abdominal pain accompanied by vomiting, and no other attack except the one immediately preceding operation,

which was described as being in the left upper quadrant. She had been slightly constipated all her life, but she had no bowel movements for two days before the hospital admission. One gets the impression that the bowels began to move again while she was in the hospital, although there is no direct mention of this.

The past history was essentially noncontributory, except for a cerebral episode, which might influence us in our diagnosis as indicating a predisposition to vascular accidents. Physical examination was not particularly striking except for evidence of an inflammatory process in the left upper quadrant. She never ran much of a temperature; the temperature on admission was 100°F, and the highest recorded was on the day of operation, when it reached 100.4°F. Immediately preoperatively there was abdominal tenderness, more marked on the right side. The white-cell count initially was 15,000, but it went down to normal. Then on the day of operation it rose again to 30,000.

A plain film of the abdomen is reported as showing several moderately dilated loops of small bowel. When I read the history up to that point it was hard for me to see how the surgeons refrained from operation with an eighteen-hour story of acute small-bowel obstruction. In that interval we know that operation carries an extremely low mortality, I believe that the incidence is a little over 1 per cent. It seems apparent that some other diagnosis was considered, and the patient treated conservatively for reasons not apparent in the record. Then we come to what I think is the most important point in the protocol, so far as differential diagnosis goes: that there was a definite abnormality in the small bowel in the form of narrowing. I should like to ask Dr. Wyman to help us decide whether that abnormality was inflammatory, neoplastic or from outside pressure.

DR. STANLEY M. WYMAN: The first film shows a loop of small bowel in the left lower portion of the abdomen, running into the right lower quadrant, and a second loop low in the pelvis. There is gas in the cecum running up to the transverse colon, and there seems to be some gas in the descending colon. I can see no areas of unusual calcification or any definite soft-tissue masses. The chest films show no more than might be expected in any person of this age. The examination of the colon shows what is apparently a normal large bowel. The Miller-Abbott tube passed through several loops of small bowel down probably to the region of the lower ileum. After barium was introduced it ran through several loops of small bowel, probably ileum, and some filtered back proximally along the tube. These are the films that are probably more important; they show the area of narrowing in the small bowel, extending distally. The bowel is constantly narrowed on several films.

DR SARRIS Do you mean to imply that the narrow area did dilate finally?

DR WYMAN I do not know. It is not mentioned in the record, and not having done the examination, I cannot say. The appearance of the lesion makes me think that it did not dilate. If we are confronted with an area of constant narrowing it is of great importance to know about the mucosal pattern. I am not sure that I can see normal mucosal pattern throughout that area. There is a suggestion of some so-called shelving here, but that is unreliable.

DR SARRIS There is no chance that the shelving was produced by extrinsic pressure?

DR WYMAN It might be extrinsic constriction, rather than a mass compressing one portion of the bowel.

DR SARRIS Is there any evidence of a foreign body, such as gallstones?

DR WYMAN No.

DR SARRIS We come then to a differential diagnosis of what causes recurrent development of pain and vomiting and causes a small-bowel picture such as we have seen. I think that we have to assume one diagnosis, since I believe we can explain it on the basis of one diagnosis. However, I think that there are two diagnoses that could explain it. Pain in the left upper quadrant in recurrent attacks in a seventy-one-year-old woman suggests recurrent pancreatitis. The story fits fairly well except for the narrowing of the small bowel. I have seen narrowing like this in the distal transverse colon from pancreatitis with fat necrosis surrounding the transverse colon causing obstruction. I have also seen it in the duodenum in a case in which there was aberrant pancreatic tissue, but I have not seen it or heard it described in the ileum and therefore I believe we cannot consider that diagnosis seriously. The history sounds reasonable for gallstone ileus until one reaches the point where the area of narrowing is described. Six weeks before entry the patient had abdominal pain and was taken to a hospital, and at that time she may have had an acute gangrenous cholecystitis with perforation into the duodenum or a loop of small bowel, and within the next few weeks she had recurrent attacks of partial intestinal obstruction from the stone in the small bowel. The x-ray picture excludes that unless the gallstone had produced an ulcerative lesion in the area of the small bowel that later became stenosed, the stones meanwhile passing. That possibility is remote. Recurrent small-bowel obstruction from a band or a Meckel's diverticulum could produce a stenotic area like this, when the bowel became ischemic but never gangrenous enough to perforate. I have seen cases of chronic intestinal obstruction following an episode of acute intestinal obstruction with ischemia of the obstructed portion of the bowel followed by stenosis after the acute episode had subsided. That is why I was hoping to be told whether or not there was a shelf. There apparently

was not one. Certainly Dr Wyman will not commit himself definitely about whether or not there was a shelf. In almost all cases a shelf means a tumor, whereas lack of a shelf makes one think of an inflammatory lesion or an ischemic lesion.

We come down to two diagnoses that must be seriously considered. The first one is mesenteric thrombosis, although in view of the suggestion of a shelf it might be less seriously considered. All patients with mesenteric thrombosis are not operated on, nor do they necessarily die without operation. We know of cases that have been explored, a thrombosis found, which was too extensive to resect, and the patient sewed up with recovery. We also know that thrombosis can produce localized areas of ischemia without perforation. I remember a case in which the patient had resection for mesenteric thrombosis, and three weeks later developed small-bowel obstruction naturally assumed to be due to faulty anastomosis, but on reoperation the anastomosis was found to be perfect, although an area of stenosis distal to the anastomosis had been produced, presumably by ischemia in that area, without complete necrosis. This picture could have been produced by mesenteric thrombosis six weeks previously, with a resultant small area of ischemia. As the bowel was stenosing down recurrent bouts of abdominal pain and vomiting occurred. Then there was the last episode of recurrent intestinal obstruction because the tube was removed, or what is more likely, another more massive attack of mesenteric thrombosis. It is well known that mesenteric thrombosis causes such recurrences.

How about regional enteritis? I should have mentioned that earlier. Isolated areas of stenosis like this do occur in regional enteritis, but I think that the patient was too old for that diagnosis.

Regarding tumors, we have sarcoma, carcinoma and carcinoid to consider. In general the picture fits very nicely with small-bowel tumor. The age is correct because the lesions tend to occur in that age group. The recurrent attacks of intestinal obstruction and vomiting, the crampy pain, the suggestion of two tarry stools—one cannot place too much reliance on the history of the two tarry stools as given by the patient—and the bleeding all occur in small-bowel tumors. The story is consistent. The final episode could have been perforation of a carcinoma or a sarcoma of the small bowel. Malignant tumors of the small bowel often perforate and produce peritonitis. If it is a tumor, of course, in general the higher up in the small bowel the more apt it is to be carcinoma, and the lower down, sarcoma. A carcinoid that one usually associates with the appendix often occurs in the small bowel, more often in the terminal ileum than anywhere else in the bowel. Carcinoid does not bleed as most malignant small-bowel tumors do. Twenty-five or 30 per cent of carcinoids of the small intestine

are often malignant as against those that occur in the appendix, which are seldom malignant.

My first choice of diagnosis in this case is a malignant tumor of the small bowel, and since it is in the lower part I can go a step farther and say sarcoma with perforation. The other distinct possibilities are any other small-bowel tumor and mesenteric thrombosis.

DR TRACY B. MALLORY: Can you tell about the opinion on the ward, Dr. Raker?

DR J. W. RAKER: There was a great deal of discussion and difference of opinion, particularly regarding the management of this patient. As Dr. Sarris suggested there was a strong feeling that she should have an operation on the day she was admitted. However, with the past history of earlier episodes and the fairly recent attack that had subsided spontaneously and the upper abdominal signs, our diagnosis that night was a possible acute pancreatitis, although there was a difference of opinion about that. Subsequently, further investigation revealed a lesion in the small bowel, and the majority of us believed that she had a small-bowel tumor and chronic cholecystitis. I believe that that was Dr. Linton's diagnosis when he explored her. The episode of pain during the last night on the ward was not particularly remarkable, and we totally missed the secondary diagnosis that was discovered.

#### CLINICAL DIAGNOSES

Small-bowel tumor  
Chronic cholecystitis

#### DR. SARRIS'S DIAGNOSIS

Malignant tumor of small bowel, with perforation immediately preoperatively

#### ANATOMICAL DIAGNOSES

*Carcinoma of gall bladder, with extension to small intestine*  
*Acute gangrenous appendicitis, with perforation and abscess formation*

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: Will you continue with the operative findings, Dr. Raker?

DR. RAKER: Dr. Linton explored the patient and discovered that she had a chronically inflamed gall bladder containing stones, which was the site of an inoperable carcinomatous process involving the liver. The lesion in the small bowel was caused by peritoneal implants on the surface of the small bowel, which had partially encircled the lumen. An unexpected finding was the presence of a perforated appendix with abscess formation in the region of the appendiceal mesentery and the mesentery of the small bowel. The loops of the small bowel involved in carcinoma were resected. It was impossible to do anything to the gall bladder. The appendix was removed, and the abscess in the region of the small-bowel mesentery was drained. Unfortunately, the wound became infected in spite of delayed closure and finally after a long period healed. However, the appendiceal abscess went on to form a large mass in the right lower quadrant that was easily palpable in the pelvis, and it was necessary to do an incision and drainage of the abscess. This was done through the right lower quadrant, and a large cavity was found and drained. The patient recovered from that and left the hospital to go to a convalescent home. We were glad that she was able to do so.

DR. MALLORY: The specimens that we received were biopsies from the carcinomatous gall bladder and two segments of small bowel, each of which was markedly obstructed by a nodule of tumor. In one of these nodules the tumor had grown through the bowel wall all the way from serosa to mucosa, and there was an ulceration of the latter. It is quite likely that the story of tarry stools and hemorrhage from the bowel was correct, though one does not expect a secondary tumor of the bowel to cause hemorrhage.

## TOTAL TRANSECTION OF THE SPINAL CORD

ATTENTION is directed to an article on the occurrence of extensor spasm in patients with a transected spinal cord printed elsewhere in this issue of the *Journal*. As the authors note, this neurophysiologic phenomenon was first given the attention it deserved outside of the experimental laboratory by Head and Riddoch. These investigators studied 8 such patients who had sustained their injuries in World War I. Their observations are authoritative and classic. They were unknowingly handicapped, however, by their inability to control urinary-tract sepsis, by their necessary lack of knowledge of the effect of proteinemia, by the confusing side effects produced by the spasm.

by the short life span of their patients. Their interpretations, moreover, were undoubtedly strongly influenced by the fundamental experimental work along these lines that had been done on animals by such a master physiologist as Sherrington.

All these circumstances combined to paint in the minds of the medical profession a picture of the response in man to accidental transection of the spinal cord that corresponded exactly with that found in experimental transection in animals. Thus it was taken for granted that after the subsidence of spinal shock all patients with transected cord would exhibit involuntary flexor as opposed to extensor spasms of the lower extremities. Spinal sweating and certain visceral manifestations, notably those affecting the urinary bladder, were thought to be associated constantly with these spasms. As a corollary the presence of involuntary extensor as opposed to flexor spasms was considered diagnostic of the less damaging partial injury of the cord and hence to warrant a better prognosis. The present authors present evidence that such a distinction, however true it may be in animals, does not hold true in man.

The fundamental studies that enabled Macht and Kuhn to collect their data have a distinct Boston tinge. Although the classic work that demonstrated the details of the activities of the normal bladder was done in London, England, one of the authors has since attached himself permanently to the Neurological Unit of the Boston City Hospital. With this work as a background there then was developed in the Neurosurgical Department of the same hospital a more accurate understanding of the mechanisms governing the spinal bladder, together with a method of treatment that reduced the mortality caused by the genitourinary-tract infection in these patients from 75 to 15 per cent.<sup>2</sup> Following this, attention was called in 1940 to the importance of a high-protein diet if the treatment of bed sores was to succeed.<sup>3</sup> This virtually abolished the other great cause of the mortality and morbidity that had been considered an indispensable accompaniment of the care of these patients. It was now possible to approach directly the problem of the "spasms." Anterior dorsolumbar rhizotomy eliminated this distressing complication and in

addition yielded extra dividends not only in the form of prolongation of life and quicker healing of bed sores but also in the possibility of ambulation and a satisfactory social life. This work, too, was all initiated and carried out at the Boston City Hospital and has since been repeated and independently confirmed at other civilian and army neurosurgical centers.

These methods were supplemented by the providential discovery of the sulfonamides and the antibiotics and, aided by the widespread use of frequent blood transfusions, saved the lives of many wounded men who would otherwise have died during their first year after wounding. Thus, for the first time a significant number of men with spinal-cord transections that were uncomplicated by infection and debility have become available for neurophysiologic observations that are comparable with the earlier similar observations hitherto limited to experimental animals. The paper by Macht and Kuhn is believed to be the first report that has been made under such properly controlled conditions in man and that deals with these fundamental responses to what amounts to an experimental injury.

It should be encouraging to those members of the profession who have neither the opportunity nor the inclination to delve into pure research and who are discouraged by the attitude of amused tolerance with which the laboratory worker regards the efforts of the practitioner to add to the sum of medical knowledge, to learn that in this instance, at least, the physiologist has been successfully challenged by the clinician. The latter has, moreover, provided as a bonus for his subjects' longer life, less sickness, hitherto unattainable ambulation and the rehabilitation of some of those to whom the world owes a great debt of gratitude.

#### "UNNECESSARY OPERATIONS"

THAT the medical profession has been guilty, wittingly or unwittingly, of ill advised therapeutic measures is common knowledge. Errors in judgment and errors caused by ignorance or misinterpretation of the patient's condition will always occur. It is the aim of physicians to reduce these costly mistakes to the lowest possible level.

In the endeavor to combat and to minimize such unnecessary operations as have been discussed by a well known popular writer in the *Woman's Home Companion*<sup>1</sup> and later abstracted for one of the foremost monthly digests,<sup>2</sup> it is perhaps inevitable that overenthusiastic and even inaccurate statements may be made. One deplores, however, such statements as the one made by a pediatrician that acute appendicitis is a rare disease in childhood but, unfortunately, appendectomy is a 'common operation'.

It is to be feared that such a statement may do a great deal of harm in the campaign so earnestly forwarded for early recognition and treatment of acute appendicitis in childhood. Only a few years ago, in Massachusetts, acute appendicitis stood high on the list of causes of death in children from one to twelve years of age. If the infant survived his first year his greatest risks before the age of twelve came from contagious disease, pneumonia, automobile accidents, and acute appendicitis, in that order, and the patients dying of acute appendicitis, almost without exception, were those in whom the disease had been unrecognized until after the appendix had ruptured and peritonitis was well established.

In the condensed article, appearing in the digest, there is a heading signed by a professor in one of the leading medical schools in the East stating "[The author] is absolutely correct in his statements. I am in favor of establishing every safeguard he mentions and many more besides."

One agrees heartily with most of the opinions expressed in this article, and perhaps necessary reform will come only as a result of overenthusiasm in presenting the facts. One regrets, however, to see a blanket statement, such as the above that the article is absolutely correct in all its observa-

## MISCELLANY

### BAY STATE NURSERY SCHOOL

The Bay State Society for the Crippled and Handicapped, in co-operation with the Boston Visiting Nurse Association, Cerebral Palsy Council of Boston, The Children's Hospital, Crippled Children's Services, Massachusetts Department of Public Health and Massachusetts General Hospital, has established a demonstration school for children with cerebral palsy at 355 Boylston Street, Boston

Twenty educable children from four to eight years of age will be accepted, following an assessment of their particular needs in relation to cerebral palsy. The school will provide physical and occupational therapy, speech instruction and parent education

## BOOK REVIEWS

*Encyclopedia of Endocrinology* Section IV Ovary Volume VII in two volumes, *Ovarian Tumors and Bibliography* By Hans Selye, M.D., Ph.D. (Prague), D.Sc. (McGill), F.R.S. (Can.), professor and director of the Institute of Experimental Medicine and Surgery, University of Montreal 4°, cloth, 289, 427 and 60 pp., with 38 plates Montreal Richardson, Bond and Wright, 1946 \$21.75

This monumental work, a small part of a general work on endocrinology of ten contemplated sections, is based on the author's library of approximately 250,000 items (reprints, abstracts, microfilms and books). The volume *Ovarian Diseases Other than Tumors* has been prepared for publication, and it is hoped that it will appear in the near future. This volume on ovarian tumors is published in two parts—text and bibliography. The text discusses in a critical manner the existing relevant literature on ovarian tumors. The subject is divided into the following sections: ovarian and paraovarian tumors in general, endocrine tumors, chorion-epitheliomas, common cysts, common carcinomas, "mesonephromas" and "Brenneromas," endometriosis, teratoids and non-epithelial tumors. The text on classification presents the schemes of Goodall, Cornill, Schiller, Novak, Miller, Geist, Taylor and that of the author used in this work. The material is well organized, written and illustrated. A good index and a list of periodicals and serials conclude the volume. The bibliography consists of approximately nine thousand references. The printing is excellent and the binding is of the loose-leaf type. The work is recommended for all medical libraries as a fundamental reference source.

*Adjustment to Physical Handicaps and Illness: A survey of the social psychology of physique and disability* By Roger G. Barker, Beatrice A. Wright and Mollie R. Gonick. 8°, paper, 372 pp. New York: Social Science Research Council, 1946 \$2.00

In this monograph the authors have brought together in a single volume what is known of the relation between social behavior and personality and the normal variation in physical size, strength, motor ability, sensory acuity and health. They have endeavored to evaluate present knowledge in the field of somatopsychology and to point out the way for future investigation. The various chapters of the text discuss the somatopsychologic aspects of normal variations in physique, the significance of crippling and impaired hearing, the social psychology of the tuberculous patient and of acute illness and the employment of the disabled. The bibliography consisting of fifty-three pages covers the various aspects of the subject discussed in the text. Two indexes of authors and subjects conclude the volume. The material is well organized, and the printing is well done with a good type on good paper. This monograph is recommended for all medical, social and general libraries. The price is surprisingly low.

*Tomorrow's Food: The coming revolution in nutrition* By James Rorty and N. Philip Norman, M.D. With a foreword by Stuart Chase. 8°, cloth, 258 pp. New York: Prentice-Hall, Inc., 1947 \$3.50

In this book a journalist and a physician have collaborated to write a history of modern diet and nutrition. The text is presented in an interesting narrative style and devotes special chapters to outstanding incidents the world over in the field of diet, principally among the so-called "common people." Their thesis is that most of the malnutrition troubles of today are due to the processing of wheat into white flour and brown sugar into white, and the use of canned milk. Their forecast for the future is bright, placing reliance on the great advances in technology, especially in food processing resulting in dehydration, the freezing and synthesizing of foods and the fortification of foods with synthetic vitamins.

Cheshire, England, lived for twenty-five years under the National Health Insurance Act. At the end of this period the six hundred panel doctors appointed a committee to determine whether the act had fulfilled its objective of "the prevention and cure of sickness." The committee and the body of physicians were unanimously convinced that on the question of cure there had been success, for the average expectancy of life had risen since the passage of the act. On the question of prevention there was positive failure, since the evidence was clear to these doctors that the illness in the community resulted from a lifetime of improper nutrition. Anemia of mothers and infants, bad teeth, rickets and constipation were prevalent. They attributed these ills to constant lifetime use of white bread, tinned salmon and dried milk. Likewise is told the stories of the Indian tribe of Hunzas and the world-wide travels of Dr. Weston A. Price in search of a people with good teeth. Wherever he found white flour, granulated sugar and canned foods, he found decayed teeth, where the diets were of natural unprocessed foods, the teeth generally were found to be in good condition without appreciable decay. The experience of the first draft for World War II revealed that 25 per cent of the first million men selected were rejected because of defective teeth, second only to poor eyes in causes for rejection. Special chapters deal with the processing of flour, sugar, milk and butter. The vitamin propaganda is frankly discussed.

The last part of the volume discusses food production from the point of view of agricultural research and distribution from the consumers' side of the question. The authors have produced an interesting book worthy of serious reading. It should find a place in all medical and public libraries.

*Textbook for Psychiatric Attendants* By Laura W. Fitzsimmons, R.N., M.A. 8°, cloth, 332 pp. New York: The Macmillan Company, 1947 \$3.50

This textbook was written primarily for attendants in mental hospitals. The text is divided into two parts. The first discusses topics of a general character, including special problems such as suicide, the use of restraint, diet, emergencies and first aid, ward housekeeping, hygiene and health, nursing care according to group classification and special therapies. The second part is given up to treatment and procedures, with a chapter on psychiatric definitions and explanations. A list of books for further reading is appended to the text. The book is well written and well published and should prove valuable to those for whom it was written.

*Tutoring as Therapy*. By Grace Arthur Ph.D. 8 cloth 125 pp. New York: The Commonwealth Fund 1946 \$1.50

This monograph discusses the individual teaching of young children of normal intellectual capacity but maladjusted because of a lack of adequate teaching at the lower grade levels, or because of some special disability prolonged illness an emotional or adjustment problem or because of some personal idiosyncrasy. The author describes her early experimental work with first grade pupils conducted in St. Paul. Other chapters have to do with the selection training and supervision of tutors, methods used to remedial teaching and tutoring as a community project. Two chapters are devoted to the discussion of a large number of illustrative cases. The material is well organized and the volume is well published in every way. This monograph should be in all school and general libraries and should prove valuable to psychologists and pediatricians.

## BOOKS RECEIVED

The receipt of the following books is acknowledged and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

*Dermatologic Clues to Internal Disease*. By Howard T. Behrman M.D., assistant clinical professor of dermatology, New York University College of Medicine adjunct dermatologist Mount Sinai Hospital and Beth Israel Hospital and associate dermatologist Hillside Hospital. 8 cloth 165 pp. with 118 illustrations. New York: Grune and Stratton 1947 \$5.00

The material in this small book is arranged alphabetically under the names of constitutional diseases exhibiting associated skin changes. The descriptions are brief and are illustrated in a large number of cases. Skin diseases of significance or of diagnostic aid in internal medicine are included, but the common skin diseases and the exanthems are excluded. The monograph is written to supply the apparent need for the correlation of skin disorders with visceral dysfunction. The price seems excessive for the size of the book despite the large number of half tones.

*A Handbook for the Diagnosis of Cancer of the Uterus by the Use of Vaginal Smears*. By Olive Gates M.D. pathologist Massachusetts State Tumor Diagnosis Service and assistant pathologist, Pondville Hospital (Massachusetts Department of Public Health) and Shields Warren M.D. assistant professor of pathology Harvard Medical School pathologist New England Deaconess and New England Baptist hospitals and reserve consultant in pathology to the Bureau of Medicine and Surgery United States Navy Captain (M.C.) U.S.N.R. With a foreword by George N. Papanicolaou M.D., Ph.D. associate professor, Department of Anatomy and research associate, Department of Obstetrics and Gynecology Cornell University Medical College and New York Hospital. 4 paper 182 pp. Cambridge Massachusetts: Harvard University Press 1947 \$4.00

The authors have prepared this handbook as a laboratory guide especially for pathologists who are interested in the vaginal smear test for cancer and find it necessary to instruct themselves in the procedure. The material is well arranged and discusses the technique of the method and its application to suspected cases. There are valuable chapters on sources of error in diagnosis and on a current appraisal of the method. The text concludes with a bibliography of current literature. An atlas of fifty plates of benign cells and malignant cells is appended to the text. The plates are exceptional in quality. The offset printing is good. This handbook should prove valuable to all physicians interested in the method.

*List of File Microcopies*. By the United States National Archives. 4 paper 31 pp. Washington D.C. The National Archives of the United States 1947 Free

In 1940 the archivist of the United States began the micro filming of important records in his care and to May 31 1947

one thousand nine hundred and eighty seven rolls of master negatives had been completed. Positives of any of these films may be had at cost from the National Archives. There has as yet not been developed any comprehensive plan and most of the microcopies have been made on special request for particular records. Some of the records already copied date back to 1790. The primary objective of the program is to make available important records to investigators at a distance from Washington. To date there have not been copied any records of medical significance although certain records of the Bureau of the Census are available.

*Ilustraciones Obstetricas*. By Doctores Gerardo Will y adjunto del Instituto de Anatomia Patologica (director M. Ascanazy) de la Universidad de Ginebra medico anatomista patologo de la Casa Municipal de Maternidad Concepcion Palacios, Caracas investigador en la Facultad de Medicina Instructor de la cátedra de Histologia Normal de la Universidad Central de Venezuela and Oscar Aguero medico-partero adjunto del Servicio No. 2 de la Casa Municipal de Maternidad Concepcion Palacios Caracas. Prologo por el Doctor Leopoldo Aguerrevere, profesor de clinica obstetrica de la Universidad Central de Venezuela. 4 paper 46 pp. Caracas: Casa municipal de Maternidad Concepcion Palacios, 1946.

This pathological atlas of obstetric conditions is based on 4,000 patients admitted to the maternity hospital in Caracas. It is the role of the hospital in perform autopsies on fatal cases resulting in a wealth of material suitable for teaching purposes. The plates are made from photographs and are in scale. The selection of subjects is good and the reproductions are exceptional. Many rare conditions are depicted: microcephalocele hydrocephalus with microcephalocele hydrocephalus, Ritter's and Werlhof's diseases hydatidiform mole, uterine rupture compression of the fetus and others, totaling twenty two pathologic conditions. The first plate is of a gravid uterus, showing the normal insertion of the placenta. The original specimens are preserved in the museum of the hospital. This fine atlas is worthy of a place in all medical libraries and should prove of interest to obstetricians.

*Medical Care and Costs in Relation to Family Income: A Statistical Source Book*. Selected and compiled by Helen Hollingsworth Margaret C. Klem and Aona M. Baney. Bureau Memorandum No. 51 Second edition 4 paper 349 pp. with 317 tables. Washington D.C. Federal Security Agency Social Security Administration Bureau of Research and Statistics 1947 \$1.25

This second edition contains the same material on the basic data on illness and the cost of medical care that were contained in the first edition. Sections on the economic characteristics on vital statistics health personnel and facilities and voluntary hospital and medical-care insurance have been added. This reference work should be in all public health and medical libraries.

Lecture Hall 9-10 a.m.

#### MEDICAL CONFERENCE PROGRAM

- Friday, March 5—Pitfalls of Roentgenologic Diagnosis  
Dr. Merrill Sosman  
Wednesday, March 10—Some Aspects of the Unipolar  
Extremity Leads of the Electrocardiogram. Particularly  
with Regard to the Q Problem. Dr. Heron Macdonald  
and Lester Joseph  
Friday, March 12—Factors in the Production of Acute and  
Chronic Severe Liver Disease. Dr. Charles S. Davidson  
Wednesday, March 17—Pediatric Clinicopathological Con-  
ference. Drs. James M. Baty and H. E. MacMahon  
Friday, March 19—Some Aspects of Auscultation of the  
Heart. Dr. Samuel Levine

Wednesday, March 24 — The Etiology of Simple Goiter

Dr Monte A Greer

Friday, March 26 — The Distribution of Amino Acids between Cells and Extracellular Fluid Dr Halvor Christensen

Wednesday, March 31 — Radioactive Phosphorus Therapy  
Dr Bruce Brown

On Tuesday and Thursday mornings from 9 00 to 10 00 Dr S J Thannhauser will give medical clinics on hospital cases. On the second and fourth Friday afternoons of each month therapeutic conferences will be held from 2 00 to 4 00 with round-table discussion, Dr R P McCombs, moderator, Dr Merrill Sosman will conduct x-ray conferences from 4 00 to 6 00. On Saturday mornings from 9 00 to 10 00 clinics will be given by Dr William Dameshek. Medical rounds are conducted each weekday except Saturday by members of the staff from 12 00 to 1 00.

All exercises are open to the medical profession

## BOSTON CITY HOSPITAL

### HOUSE OFFICERS' ASSOCIATION

The House Officers' Association of the Boston City Hospital will present a lecture in its Tuesday evening lecture series in the New Cheever Amphitheater of the Dowling Building, Boston City Hospital, on Monday, March 8, at 7 p m. Dr Frank Horsfall will speak on the subject "Primary Atypical Pneumonia."

All interested persons are cordially invited to attend

## AMERICAN CONGRESS OF PHYSICAL MEDICINE

The spring session of the Eastern Section of the American Congress of Physical Medicine will be held at Jefferson Medical College, Philadelphia, on Saturday, April 10, at 2 p m.

There will be a symposium on the "Effect of Physical Inactivity and of Exercise" in the afternoon and a round-table discussion on "Low Back Pain and the Sciatic Syndrome" in the evening at Benjamin Franklin Hotel.

## SUFFOLK CENSORS' MEETING

The censors of the Suffolk District Medical Society will meet for the examination of candidates at the Boston Medical Library, 8 Fenway, on Thursday, May 6, at 4 p m.

## AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY, INC

The general oral and pathology examinations (Part II) for all candidates will be conducted in Washington, D C, by the American Board of Obstetrics and Gynecology from Sunday, May 16, through Saturday, May 22. The Shoreham Hotel in Washington will be the headquarters. Formal notice of the exact time of each candidate's examination will be sent him several weeks in advance of the examination dates. Hotel reservations may be made by direct application in writing to the Shoreham Hotel.

Candidates for re-examination in Part II must make written application to the Secretary's office not later than April 1.

Candidates in military service are requested to keep the Secretary's office informed of any change in address.

Applications will be received until November 1, 1948, for the 1949 examinations.

For further information and application blanks address Paul Titus, M D, Secretary, 1015 Highland Building, Pittsburgh 6, Pennsylvania.

## INTERNATIONAL CONGRESS ON MENTAL HEALTH

An International Congress on Mental Health will be held in London, England, from August 11 to 21, 1948. The Congress will consist of three international conferences: "Child Psychiatry" (theme, personality development in its individual and social aspects with special reference to aggression), "Medical Psychotherapy" (theme, guilt)—these two

conferences will run concurrently from August 11 to August 14 and "Mental Hygiene" (theme, mental health and world citizenship), which will run from August 16 to August 21. The last conference will form the major part of the program. The following subdivisions of the general theme will be the main topics on consecutive days: problems of world citizenship and good group relations, the individual and society, family problems and psychological disturbance, planning for mental health (organization, training, propaganda), mental health in industry and industrial relations, and concluding session and summaries.

This conference is sponsored by the International Committee for Mental Hygiene, Inc, 1790 Broadway, New York 19, New York.

## REFRESHER COURSES FOR OFFICERS OF THE NAVY MEDICAL CORPS RESERVE

Refresher courses in medicine, surgery, obstetrics and gynecology, for reserve officers of the Navy Medical Corps, will begin at Chelsea Naval Hospital on March 28. The courses will be of two weeks' duration, the final period ending in May. Full pay and allowances in grade will be paid for the two-week period of active duty. Quarters are not available at the hospital and must be arranged for privately. Thirty medical corps officers will be admitted to each two-week period.

The refresher program will be supervised by the regular staff of the hospital, augmented by the consulting staff.

Applications for participation in the program should be mailed to District Medical Officer, First Naval District Headquarters, Navy Building, 495 Summer Street, Boston 10, Massachusetts.

## SOCIETY MEETINGS AND CONFERENCES

### CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, MARCH 11

#### FRIDAY, MARCH 12

\*9 00-10 00 a m Factors in the Production of Ascites and Edema in Severe Liver Disease Dr Charles S Davidson Joseph H Pratt Diagnostic Hospital

\*10 00 a m-12 00 m Medical Staff Rounds Peter Bent Brigham Hospital

**PRECISION  
BUILT by  
Expert Craftsmen**

The knee-joint cross section shows that Hanger Artificial Limbs are not complicated mechanisms, not loosely fitted pieces, but a few expertly machined parts carefully assembled by experts. The simple construction making possible the efficient operation of Hanger Limbs is the result of long study and research. It is dependent on precision made parts properly assembled. Hanger craftsmen are carefully selected and trained for this important work. Each Hanger Limb therefore conforms to specifications developed by years of experience.

## Old Way...

### CURING RICKETS in the CLEFT of an ASH TREE

FOR many centuries,—and apparently down to the present time, even in this country—ricketic children have been passed through a cleft ash tree to cure them of their rickets, and thenceforth a sympathetic relationship was supposed to exist between them and the tree.

Frazer\* states that the ordinary mode of effecting the cure is to split a young ash sapling longitudinally for a few feet and pass the child, naked, either three times or three times three through the fissure at sunrise. In the West of England, it is said the passage must be "against the sun." As soon as the ceremony is performed, the tree is bound tightly up and the fissure plastered over with mud or clay. The belief is that just as the cleft in the tree will be healed, so the child's body will be healed, but that if the rift in the tree remains open, the deformity in the child will remain, too, and if the tree were to die, the death of the child would surely follow.

\*Frazer J. G.: *The Golden Bough*, vol. 1. New York, Macmillan & Co., 1922.

It is ironical that the practice of attempting to cure rickets by holding the child in the cleft of an ash tree was associated with the rising of the sun, the light of which we now know is in itself one of Nature's specifics.

## New Way...

### Preventing and Curing Rickets with OLEUM PERCOMORPHUM

NOWADAYS, the physician has at his command, Mead's Oleum Percomorphum, a Council-Accepted vitamin D product which actually prevents and cures rickets, when given in proper dosage.

Like other specifics for other diseases, larger dosage may be required for extreme cases. It is safe to say that when used in the indicated dosage, Mead's Oleum Percomorphum is a specific in almost all cases of rickets, regardless of

degree and duration. Mead's Oleum Percomorphum because of its high vitamins A and D content is also useful in deficiency conditions such as tetany, osteomalacia and xerophthalmia.

\* \* \*

#### COUNCIL-ACCEPTED

Oleum Percomorphum With Other Fish Liver Oils and Viosterol. Contains 60,000 vitamin A units and 8,500 vitamin D units per gram and is supplied in 10 c.c. and 50 c.c. bottles; and in bottles containing 50 and 250 capsules.

**MEAD JOHNSON & COMPANY, Evansville, Indiana, U. S. A.**

## TOTAL PANCREATECTOMY\*

EUGENE A. GASTON, M.D.†

FRAMINGHAM, MASSACHUSETTS

AN INCREASING interest in surgery of the pancreas has been manifested since the demonstration by Whipple,<sup>1</sup> in 1935, of the practicability of partial pancreatectomy for the relief of cancer arising in or about the head of the pancreas. A natural outgrowth of this interest is recent efforts aimed at the feasibility of total pancreatectomy not only for the elimination of more extensive cancers but also for the relief of certain types of benign pancreatic disease. To date 16 cases of total pancreatectomy have been reported in the literature. Because the physiologic changes incident to total pancreatectomy in man are as yet imperfectly understood, it is important that observations made during and subsequent to this type of surgery be reported, so that the accumulated experience may eventually permit evaluation of its proper place in treatment. The purpose of this communication is to review the pertinent literature and to present a case of carcinoma involving the entire pancreas recently treated at the Framingham Union Hospital. In addition to resection of all of the pancreas the following structures were removed at operation: the spleen, the pyloric antrum of the stomach, all of the duodenum, 15 cm. of jejunum, the lower half of the common bile duct and the right half of the transverse colon.

### CASE REPORT

A 70-year-old man was admitted to the hospital on May 23, 1947, complaining of upper abdominal pain of 4 months' duration. Two years before admission the patient had begun to limit his diet without medical advice, because of obesity. This was followed by gradual loss of weight, which had become somewhat accelerated during the last 4 months and which totaled 32 pounds. One year before admission the gradual onset of constipation was noted. This became gradually worse and during the last 6 months required a daily enema. Occasional tarry stools had been noted but there had been no gross blood. Four months before admission he applied strong pressure to the lower sternal and epigastric regions in using a heavy electric drill which "shook him up" considerably. Four hours later he noted the sudden onset of epigastric pain which since then had been more or less constantly present and which was described as a gnawing

sensation radiating to the midline of the lower dorsal region. The pain was aggravated by food was partially relieved by sitting or standing and by pressure applied to the epigastrium and was not affected by alkalis. One month before admission an x-ray diagnosis of duodenal ulcer was made at another institution and the patient was placed on a six meal bland diet without relief. Two weeks before admission increasing pallor and weakness associated with some dyspnea on exertion was noted. At about that time he also noted slight itching of the skin. The urine was dark, although the stools were normal in color or occasionally tarry black. On the day of admission while driving his car he suddenly became disoriented and somewhat disoriented. This condition persisted for about 2 hours after which his mental state gradually returned to normal. The patient was known to have had hypertension for about 6 months but when he was seen by a physician after this episode, the blood pressure was found to be 125/70.

A review of the systems indicated no symptoms except a history of several years' duration. The past and family histories were noncontributory.

Physical examination revealed an elderly, thin, pale man with no distress. There was a slight icteric tint to the skin and sclerae. The head, neck, and chest were normal. The heart was not enlarged, rhythm was regular and there were no murmurs. The lungs were clear. The abdomen was soft and readily examined. There was slight tenderness in the midline between the xiphoid and umbilicus but no muscle spasm or rebound tenderness. No masses were palpable. The genitalia and extremities were normal; the prostate was not palpably enlarged, and no masses were felt by rectum.

The temperature, pulse and respirations were normal. The blood pressure was 140/70.

The specific gravity of the urine varied from 1.003 to 1.016. Bile was present in each of seven specimens, but there was no albumin or sugar. Except for an occasional white cell the sediment was normal. No urobilinogen was found in either of two specimens tested. Examination of the blood disclosed a red-cell count of 2,050,000 with a hemoglobin of 6.5 gm. per 100 cc. and a white-cell count of 5600. The blood smear was normal except for moderate hypochromia. The blood sugar was 141 mg. per 100 cc. on the day after admission and 95 mg. several days later. The nonprotein nitrogen was 56 mg. per 100 cc. on admission falling to 37 mg. on the day before operation. The total protein was reported as 6.0 gm. per 100 cc. with an albumin globulin ratio of 4:1. After the transfusion of 4500 cc. of blood over the following 12 days, the total protein was 8.0 gm. per 100 cc., with an albumin globulin ratio of 1:1. The prothrombin time was within normal limits and the initial icteric index was 16. Two attempts to determine the total blood volume by the use of the dye T 1824 were frustrated by the presence of jaundice which made it impossible to obtain satisfactory colorimetric readings. The presence of the blue dye in the blood serum made it impossible to secure satisfactory readings of the icteric index subsequent to admission although clinically the patient became progressively more jaundiced. Each of nine stool specimens was strongly positive for occult blood and one was reported to be negative. The stools were brown during the early part

\*From the Surgical Service, Framingham Union Hospital and the Department of Surgery, Boston University School of Medicine.  
†This study was aided by the Research and Publication Fund of the Framingham Union Hospital.

†Assistant Professor of Surgery, Boston University School of Medicine, Framingham Union Hospital.

of the hospital stay but became clay colored thereafter. Gastric analysis revealed no free hydrochloric acid.

Electrocardiographic tracings disclosed left-axis deviation but were otherwise normal. X-ray examination of the chest showed the lungs to be clear, the heart was not enlarged. A barium enema demonstrated that the colon was normal. The esophagus and stomach were normal on gastrointestinal x-ray study. There was definite widening of the duodenal loop, indicating enlargement of the head of the pancreas. The duodenal mucosa revealed no evidence of ulceration, a cholecystogram was not done because of the presence of jaundice.

The patient was studied for 12 days preceding operation, during which the temperature, pulse and respirations were within normal limits. The blood pressure gradually rose

bile duct was freed from the portal vein and hepatic artery and divided in its supraduodenal portion, the portal vein was accidentally lacerated but was satisfactorily repaired. The neck of the pancreas was easily freed from the underlying portal and superior mesenteric veins. The uncinate process was small and not adherent to the superior mesenteric vessels and was easily dissected free. At this point it was found that the blood supply to the transverse colon was anomalous and that the vessels supplying the right half extended through the neoplastic mass in the head of the pancreas. After the duodenum had been divided at the ligament of Treitz and mobilized to the right under the superior mesenteric vessels, the anomalous vessels to the right half of the transverse colon were divided, completing the mobilization of the duodenum and the head of the

FIGURE 1 The Diabetic State after Total Pancreatectomy

from 140/70 on admission to 200/90 on the day before operation. The icterus became progressively deeper, the urine continued to show the presence of bile, and the stools changed from brown to clay colored. Food and fluids were well tolerated, and the diet was supplemented by daily intramuscular injections of crude liver extract, vitamin C and vitamin K. The prothrombin time did not vary significantly from the normal. Although the patient had Type A, Rh— blood, a total of 4500 cc of whole blood was given without reaction, and at the end of the preoperative period he was considered to be a fair operative risk.

Operation was performed June 5 under continuous spinal anesthesia supplemented with intravenous Pentothal Sodium and small amounts of ether. A long, right-rectus-muscle-splitting incision was made and later enlarged by a connecting transverse incision extending across the upper abdomen to the left costal margin. The entire head, neck, body and tail of the pancreas were indurated, apparently owing to diffuse invasion by a neoplastic process that had not grossly invaded the surrounding structures. The liver was dark from jaundice and slightly enlarged but contained no metastatic nodules. The gall bladder was thin walled and markedly distended with thick, black bile, which was aspirated to facilitate exposure. The common bile duct was about 1.5 cm. in diameter. After the gastroduodenal omentum had been divided a biopsy of the middle of the body of the pancreas was submitted to Dr. C. G. Tedeschi for frozen-section examination and was reported as showing the presence of carcinoma. Since the entire pancreas was obviously involved a total pancreatectomy was decided upon.

The stomach was divided about 7.5 cm. proximal to the pyloric sphincter, and the duodenum mobilized. The gastroduodenal vessels were identified and divided. The common

pancreas. Exposure for the mobilization of the body and tail of the pancreas was then greatly facilitated by division of the pancreas at its neck and removal of the mobilized pyloric antrum, duodenum and head of the pancreas. It was then evident that the splenic vessels were surrounded by neoplastic tissue. The spleen was therefore mobilized by division of the short gastric and left gastroepiploic vessels. The splenic artery and vein were divided close to their points of origin, and the body and tail of the pancreas and the spleen were removed.

About 15 cm. of jejunum distal to the ligament of Treitz had been resected to assure an adequate blood supply, the end of the jejunum was closed. A loop of proximal jejunum was brought through a rent in the transverse mesocolon, and end-to-side anastomoses were completed between the jejunum and the stumps of the stomach and common bile duct, the latter about 10 cm. distal to the former. After these had been completed it was evident that the blood supply to the right half of the transverse colon was inadequate. The hepatic flexure of the colon was mobilized, and the right half of the transverse colon delivered through the middle of the wound and amputated over clamps to form a double-barreled colostomy. A catheter was sutured into the gall bladder and brought out through a stab wound in the right flank. A rubber tissue drain was placed in the bed of the pancreas and brought out through a second stab wound in the right flank. The wound was closed around the two loops of the transverse colostomy.

During the operation, which required 6½ hours, the patient received 2300 cc of 5 per cent glucose in distilled water, 1500 cc of whole blood and 300 cc of plasma. The anesthesia required 455 mg of procaine, 52 mg of pontocaine, 1.5 gm of Pentothal Sodium and 28.3 gm of ether. The patient

withstood the operative procedure remarkably well but when the operation had been completed the pulse rate was 130 and the blood pressure 90/55.

The immediate postoperative response to continued intravenous therapy was very satisfactory; the pulse rate and blood pressure rapidly approximating preoperative levels.

careful attention to the diabetic state since the entire pancreas had been removed.

The first 4 days of the postoperative course were remarkably smooth. The temperature and pulse curves progressively fell toward normal; peristalsis returned on the fourth day and the patient was mentally alert and physically active.

FIGURE 3

A shows specimen from ulcerated area in second portion of duodenum illustrating normal duodenal glands and closely adjacent adenocarcinoma. B demonstrates section from head of pancreas showing extensive malignant infiltration. C illustrates portion from tail of pancreas showing dilated ducts, one of which contain a clump of malignant cells (note enlargement of pancreatic islets). D demonstrates liver showing some but not marked fatty replacement.

Postoperative treatment consisted in decompression of the gastrointestinal tract by means of suction applied to a Levine tube which was continued for 4 days; the administration of adequate intravenous fluids including glucose, physiologic saline solution, protein hydrolysate, plasma and whole blood (a total of 4000 cc. of blood during and after operation); penicillin and streptomycin in large doses; and

The proximal loop of the colostomy was opened at that time and the wound appeared to be clean. On the evening of the 11th day the temperature rose to 101 F. and on the following day sepsis around the distal loop of the colostomy was discovered. The wound was opened and extensive undermining by pus was discovered between the intact peritoneum and the overlying muscle. The entire septic area was widely

opened, cultured and packed with gauze, which was kept saturated with a mixture of urethane and penicillin.<sup>2</sup> At the same time the dose of penicillin, which until then had been 100,000 units every 3 hours, was increased to 500,000 units every 3 hours, to which 500 mg of streptomycin was added. In spite of the most vigorous treatment the temperature and pulse continued to rise, and the patient became disoriented and finally comatose and died on the 8th postoperative day. The urinary output was maintained between 1200 and 2400 cc daily, and yet the nonprotein nitrogen remained elevated to between 50 and 60 mg per 100 cc until the day before death, when it rose to 70, reaching 107 mg per 100 cc on the day of death. Throughout the postoperative course the serum chloride remained within normal limits, varying from 550 to 620 mg per 100 cc. The cholecystostomy drained relatively small amounts of bile, the maximum being 320 cc on the 2nd postoperative day. The icteric index fluctuated between 49 and 59 until the day of death, when it reached 75.

The postoperative diabetic state was followed closely. Fresh urine specimens were tested hourly for sugar and diacetic acid for 3 days and every 3 hours thereafter. The blood sugar level and carbon dioxide combining power were determined daily. At no time did the urine show diacetic acid, and the carbon dioxide combining power was consistently within normal limits, ranging from 53 to 69 vol per cent. Figure 1 shows graphically the relation of the levels of sugar in the blood and urine to the administration of insulin, intravenous glucose and protein hydrolysate. As in other cases of total pancreatectomy this patient proved to be relatively mildly diabetic. Because of the increased sensitivity to insulin reported after total pancreatectomy, efforts in the treatment of the diabetes were directed to the prevention of acidosis rather than to the maintenance of normal blood sugar levels.

It will be noted from Figure 1 that in spite of the administration of 115 gm of intravenous glucose during operation only 20 units of insulin was given during the next 17 hours. At the end of that period the blood sugar level was 101 mg per 100 cc. During the next 30 hours during which neither glucose nor insulin was administered, the urinary excretion of sugar fell to zero, and the blood sugar remained within normal limits. The largest amount of insulin required during any 24-hour period was during the 4th postoperative day, when a total of 30 units was given. From the 5th to the 8th postoperative day there was a progressive rise in blood sugar levels that was probably related not only to the increased administration of glucose and protein hydrolysate but also to the onset of sepsis.

Because of the short period of survival following the operation, there was no opportunity to make observations on the effects of elimination of other pancreatic secretions. However, on the 5th day after operation the serum lipase was reported as 0.1 cc N/20 NaOH (normal, 0.1 to 1.0 cc).

The surgical specimen consisted of the distal 6 cm of stomach, all of the duodenum and an additional 10 cm of upper jejunum, all of the pancreas and spleen and 24 cm of transverse colon. The resected stomach and jejunum showed no gross or microscopical abnormalities. The transverse colon showed gross and microscopical evidence of infarction (due to ligation of its blood supply at operation) with widespread hemorrhagic changes and vascular congestion affecting all coats, the mucosa most severely. The entire head, body and tail of the pancreas were indurated and of variegated appearance due to alternating yellowish-pink, lobulated areas still preserving the characteristics of pancreatic tissue, and of grayish-pink translucent areas suggesting neoplastic tissue. An area of indurated ulceration 2 cm in diameter was found on the lesser curvature of the second portion of the duodenum. On microscopical examination this area of the duodenum, as well as the entire pancreas, showed evidence of a neoplastic process characterized by atypical glandular structures and by anaplastic cells disposed in cords or in rudimentary alveoli imbedded in fibrous connective tissue. The pancreatic islands were well preserved and, particularly in the region of the tail, appeared to be larger than normal (Fig 2A, B and C). The spleen showed no gross or microscopical abnormalities.

Autopsy was performed 1¼ hours post mortem. About 200 cc of purulent, blood-tinged fluid was found encysted between the lesser curvature of the stomach and the liver.

From this fluid were cultured *Escherichia coli*, *Proteus vulgaris* and *Pseudomonas aeruginosa*. A second area of encysted fluid, containing about 600 cc, was observed in the bed of the removed spleen. This fluid was watery and blood tinged and was not infected. The remainder of the abdominal cavity was clean. The gastrojejunal and cholodochojejunal anastomoses were well healed and patent.

The liver was somewhat enlarged, weighing 1500 gm, and except for moderate jaundice disclosed no gross abnormalities. On microscopical examination the liver cells in the center of the lobules showed regressive changes ranging from cloudy swelling to fatty degeneration, which, however, was moderate and did not compare with the extensive changes noted in a depancreatized dog (Fig 2D). Bile casts were noted as well as a patchy distribution of inflammatory cells, chiefly lymphocytes and histiocytes. The Kupffer cells stood out conspicuously, and many were seen to contain blocks and granules of yellowish-brown pigment.

No gross evidence of metastasis was found. However, on microscopical examination small clumps of neoplastic cells similar to those found in the pancreas were found in both the cortex and the medulla of the left adrenal gland. Other important autopsy findings were generalized atherosclerosis, hypertrophy and dilatation of the left ventricle, myocardial fibrosis, left hydrothorax, pulmonary congestion and edema, purulent bronchitis and bronchiolitis and renal arteriosclerosis.

## SURGICAL RESULTS

The first authenticated case of total pancreatectomy was reported by Rockey<sup>3</sup> in 1943. This operation was performed for carcinoma arising in the body of the pancreas. The patient survived fifteen days, succumbing to bile peritonitis due to a "blow out" of the ligated end of the common bile duct. Of historical interest only are 2 cases culled from the literature by Sauve<sup>4</sup> in both of which nearly total pancreatectomies were done. The first of these was credited to Billroth by Mayo-Robson in 1901, the operation having been done in 1884. Since this case was never fully reported the exact extent of the operation and the end result are unknown. The second case was reported by Franke in 1900. This operation was also done for cancer of the pancreas, but the duodenum was not removed and a mass of pancreatic tissue "the size of a hazel nut" was left behind. Only transient glycosuria developed rather than severe diabetes as might have been expected from recent experimental findings discussed below. The patient survived five and a half months, dying from recurrent cancer.

The 16 reported cases of total pancreatectomy, together with the case presented above, are described in Table 1. Eleven operations were done for cancer, and only 3 patients survived the immediate postoperative period—an operative mortality of 73 per cent. Of the 3 who survived operation, 1 died in three and a half months of carcinomatosis, the second was living without known recurrence four months after operation, and the third was living with probable recurrence fifteen months after operation. It appears that the efficacy of total pancreatectomy for the cure of malignant tumors remains to be demonstrated. Of the 6 patients with benign disease, 4 were operated upon for pancreaticolithiasis, with an operative mortality of 50 per cent. Of the 2 survivors, 1 died of an in-

sulin reaction at the end of two and a half months, and the other was alive and free of abdominal pain a year after operation, but institutionalized because of pulmonary tuberculosis. Pancreatectomy was performed in the remaining 2 cases because of hyperinsulinism due to islet-cell adenomas that were small and so buried in the head of the pancreas that they could not be demonstrated at operation. At the time of the reports both patients were living and well, 1 thirty-seven months<sup>8</sup> and the other eight months<sup>8</sup> after operation. In the 17 cases of total pancreatectomy for all causes, 7 patients survived operation and 10 died, an operative mortality of 59 per cent.

Although, to date, the surgical mortality and the end results of total pancreatectomy leave much to be desired, it is probable that with increasing experience cure rates may be elevated and mortality figures reduced to acceptable limits. This has certainly been the experience with many operative procedures — for instance, with total gastrectomy — during recent years.

#### PHYSIOLOGIC CHANGES

##### *The Diabetic State*

The diabetic state that follows total pancreatectomy in man appears to be relatively mild. In the first case of total pancreatectomy, reported by Rockey,<sup>3</sup> the patient was given 67 units of insulin to cover intravenous glucose on the day of operation and 93 units on the following day. These doses were followed by severe and prolonged insulin reactions. Eventually, the daily insulin requirement was found to be only 27 units. Since then many authors have noted the relatively low insulin dosage required during the immediate postoperative period. To date only 7 patients have survived for longer periods, and these cases are listed in Table 2 along with the daily food intake and insulin requirement. In these cases the average daily insulin requirement was about 42 units, with a carbohydrate intake that averaged 289 gm.

Of particular interest in this connection are the cases reported by Brunschwig and his associates<sup>10</sup> and by Dixon et al.<sup>11</sup> In both these cases diabetes was present before total pancreatectomy was done. One patient, a fifty-three-year-old man, had had known diabetes for nine months preceding operation.<sup>10</sup> During the preoperative period, during which his weight was 72 kg (158 lb), the diabetes was controlled by 40 to 65 units of insulin per day on a diet of 398 gm of carbohydrate, 200 gm of protein and 12 gm of fat (glucose equivalent of 511 gm). Two months after operation the insulin requirement was reduced to about 40 units per day on a diet of 401 gm of carbohydrate, 102 gm of protein and 11 gm of fat (glucose equivalent of 459 gm). At that time the body weight had fallen to 56 kg (123 lb). The authors point out that the apparent reduction in the demand for insulin may have been due to two factors: the lower glucose value

of the postoperative diet and the loss of 16 kg of weight. The striking fact, however, is not that the insulin requirement was not more greatly reduced but that it was not greatly augmented by total pancreatectomy. From these observations the authors conclude that the insulin production of the normal pancreas is in the range of 30 to 50 units per day and that in diabetic patients requiring more than this amount, an extrinsular factor must be contributing to the diabetic syndrome.

The patient of Dixon et al.<sup>11</sup> was a fifty-year-old man who had known diabetes of nineteen months' duration before total pancreatectomy. During the preoperative period the diabetes was controlled with 24 units of protamine-zinc insulin daily. Seven months after operation 40 units of protamine-zinc insulin daily was required.

These and other observations have led to speculation regarding whether clinical diabetes, which often requires doses of insulin far in excess of those reported after total pancreatectomy, is entirely due to degeneration of insular tissue. Goldner and Clark,<sup>9</sup> after observations in 2 cases of total pancreatectomy with shorter survival periods, state that "The question must be raised whether in the causation of diabetes not only lack of insulin but also an insulin-inhibiting mechanism may play a role." Experimental evidence pointing in this direction was presented by Dragstedt, Allen and Smith,<sup>12</sup> who found the insulin requirement of partially depancreatized dogs to exceed that required after total pancreatectomy. Sprague,<sup>6</sup> however, believes that even if the insulin requirement of the depancreatized human being proves to be consistently less than that of many patients with severe diabetes, the conclusion that spontaneous diabetes and surgical diabetes are basically different is not justified. He points out that the insulin requirement in spontaneous diabetes is subject to a wide variety of influences, one of the most important of which is cachexia from any cause, which not only reduces the requirement for insulin but also may even lead to hypoglycemic coma without the administration of insulin. The poor nutritional state of patients after total pancreatectomy may well tend to ameliorate the diabetes and lower the insulin requirement. Furthermore, nothing is known of the effect of total pancreatectomy on the glycogenic and glycolytic functions of the liver, alterations of which might profoundly affect the diabetic state.

A state of apparently increased sensitivity to insulin has been present during the early postoperative period in nearly all reported cases, and Clagett's<sup>13</sup> patient died of an insulin reaction two and a half months after operation. These observations are of great importance in the management of patients after total pancreatectomy. It is evident that treatment during this period should be directed more toward the prevention of ketosis than to the control of the blood sugar levels. To date no case of

insulin resistance has been reported after total pancreatectomy

Evidence that ketogenesis follows total pancreatectomy in man is scanty but indicates a similar-

withdrawn Glycosuria and ketosis promptly appeared, and death occurred in typical diabetic coma six days later Dixon's<sup>6</sup> case was studied during two periods of insulin deprivation of eighty-nine

TABLE 1 Cases of Total Pancreatectomy Reported in the Literature

CASE No	AUTHOR	SEX	AGE	DIAGNOSIS	OTHER OPERATIVE PROCEDURES	SURVIVAL	CAUSE OF DEATH
1	Rockey <sup>8</sup>	M	51	Adenocarcinoma arising in body of pancreas	Partial (distal half) gastrectomy, total duodenectomy	15 days	Bile peritonitis due to "blow out" of ligated common bile duct
2	Priestly et al. <sup>8</sup> Vaugh et al. <sup>8</sup>	F	49	Hyperinsulinism due to islet-cell adenoma	Partial (distal third) gastrectomy, partial (first and second portions) duodenectomy	Patient living and well 37 mo after operation	—
3	Brunschwig <sup>7</sup> (Case H H 302199)	M	67	Carcinoma of entire pancreas	Total duodenectomy, splenectomy	3 days	Massive bilateral pulmonary consolidation
4	Brunschwig <sup>7</sup> (Case N R. 309791)	M	29	Diffuse carcinoma of pancreas	Total duodenectomy, splenectomy	9 days	Exhaustion
5	McClure <sup>8</sup> (Case of Fallis)	M	46	Primary carcinoma of pancreas	Total duodenectomy, splenectomy	Patient living and well 4 mo after operation	—
6	Goldner and Clark <sup>8</sup> (Case of Brunschwig)	Not stated	Not stated	Carcinoma of bile duct invading pancreas	Not stated	11 days	Gastric hemorrhage, early peritonitis
7	Goldner and Clark <sup>8</sup> (Case of Clark)	M	45	Papillary carcinoma of common bile duct with invasion into head of pancreas chronic pancreatitis	Partial duodenectomy, pylorotomy, splenectomy	10 days	Hepatorenal failure and uremia
8	Brunschwig et al. <sup>10</sup> Ricketts et al. <sup>11</sup> Ricketts et al. <sup>12</sup> (Case F W 328218)	M	53	Carcinoma arising in body of pancreas with extension to stomach and left adrenal gland, metastasis to lymph nodes	Total gastrectomy, total duodenectomy, splenectomy, left adrenalectomy, omentectomy	3½ mo	Carcinomatosis and diabetic coma due to insulin withdrawal
9	Whipple <sup>13</sup>	F	26	Chronic pancreatitis, pancreaticolithiasis	Pylorotomy, total duodenectomy	Patient alive, with pulmonary tuberculosis 1 yr after operation	—
10	Whipple <sup>13</sup>	F	46	Fibrosis of pancreas, pancreaticolithiasis	Pylorotomy, total duodenectomy, splenectomy	7 days	Shock and pulmonary edema
11	Zininger <sup>14</sup>	M	39	Chronic pancreatitis, pancreaticolithiasis	Not stated	30 hr	Not stated
12	Brunschwig <sup>15</sup>	Not stated	Not stated	Carcinoma of pancreas	Not stated	14 days	Not stated
13	Vaugh et al. <sup>8</sup>	F	36	Hyperinsulinism due to islet-cell adenoma	Pylorotomy, partial duodenectomy	Patient living and well 8 mo after operation	—
14	Dixon <sup>16</sup>	M	50	Carcinoma arising in head and involving half of pancreas remainder atrophic	Partial gastrectomy (distal half), total duodenectomy, splenectomy	Patient living with recurrent cancer 14 mo after operation	—
15	Clagett <sup>17</sup>	F	37	Chronic pancreatitis, diffuse calcification of pancreas multiple pancreatic calculi	Partial gastrectomy, partial duodenectomy, splenectomy	2½ mo	Insulin reaction
16	Brunschwig <sup>18</sup> (Case 348369)	Not stated	Not stated	Sarcoma — origin not stated	Subtotal (seven eighths) gastrectomy, total duodenectomy, splenectomy, transverse colectomy	19 days	Peritonitis due to leakage of gastrojejunostomy anastomosis
17	Gaston	M	70	Adenocarcinoma probably arising in papilla of Vater and invading entire pancreas	Pylorotomy, total duodenectomy, splenectomy, transverse colectomy	8 days	Peritonitis secondary to wound sepsis uremia

ity to that produced in untreated spontaneous diabetes and in depancreatized dogs. The patient of Brunschwig<sup>10, 11</sup> developed recurrent cancer, and three and a half months after operation, insulin was

hours each, the first beginning on the sixty-sixth and the second on the two hundred and forty-fifth postoperative day. During the first interval the diet contained 440 gm of carbohydrate daily, and

whereas the blood sugar level rose to 813 mg per 100 cc, the carbon dioxide combining power remained within normal limits and the urine showed a faint trace of acetone only during the last eight

chloride by mouth. In spite of a large urinary output the blood urea rose to 57 mg per 100 cc. During the second interval of insulin privation the diet contained only 120 gm of carbohydrate, and a salt

TABLE 1 (Continued)

CASE No.	DIET	DAILY INSULIN	EXTERNAL PANCREATIC SECRETION STUDIES	PLASMA LIPIDS	LIVER AND LIVER FUNCTION STUDIES	REMARKS
1	—	27 units (frequent insulin shock 1 early post-operative period)	—	—	Liver normal at autopsy	Slightly less than 1 gm. of pancreatic tissue found at autopsy
2	Carbohydrate 243 gm.; protein 94 gm.; fat, 70 gm.	30 units	Recovered in feces 35-70 per cent. + coated fat, 5-5 per cent of ingested nitrogen; recovered in urine and feces 21-34 per cent. + coated calori	Normal 37 mo. after operation	Bromsulphalein retention normal 30 mo. after operation	—
3	—	—	—	—	—	—
4	—	Less than anticipated	—	—	—	—
5	—	26 units of protamine zinc insulin daily 8 units of regular insulin twice weekly	—	—	—	—
6	150 to 200 gm. of glucose parenterally	50 units	—	—	—	—
7	150 to 200 gm. of glucose parenterally	30 to 40 units	—	—	—	Neoplasm extended into wall of portal vein and around celiac axis preventing complete eradication
8	Carbohydrate, 401 gm; protein 102 gm.; fat, 11 gm.	30 units of protamine zinc insulin 10 units of regular insulin (frequent hypoglycemic reactions)	—	Slowly declined but never abnormal	Liver fatty at autopsy probably owing to death in diabetic coma	Patient diabetic before operation requiring more insulin than after operation; pre-operative diabetes spot tanes and not due to tumor
9	Carbohydrate, 300 gm.; protein 70 gm.; fat, 75 gm.	30 to 80 units	—	—	—	—
10	—	50 to 90 units (failed to control glycosuria)	—	—	—	Autopsy revealed localized bile peritonitis and thrombosis of large branch of portal vein
11	—	30 to 50 units	—	—	—	—
12	—	Not stated	—	—	—	—
13	Carbohydrate 267 gm.; protein 125 gm.; fat, 103 gm.	26 units of regular insulin 6 units of protamine-zinc insulin	—	Normal 70 days postoperatively slightly below normal 123 days postoperatively; probably due to jaundice	—	—
14	Carbohydrate, 272 gm.; protein 107 gm.; fat 100 gm.	30 units of regular insulin 10 units of protamine-zinc insulin	Nitrogen loss in stool 4 to 8 gm. (normal less than 1.5 gm.); fat loss in stools 36 to 48 gm. (normal 6 to 7 gm.)	Increase of 100 per cent 8 mo. after operation	Bromsulphalein retention normal 8 mo. after operation	Patient diabetic 19 mo. before operation requiring 30 units of insulin daily
15	Carbohydrate 250 gm.; protein 75 gm.; fat, 101 gm.	30 units of regular insulin 8 units of protamine zinc insulin	—	Normal 1 mo. after operation	Bromsulphalein retention normal 1 mo. after operation	Prolonged drainage of common bile duct did not relieve symptoms before pancreasectomy
16	—	Diabetes did not appear unusually severe or difficult to control	—	—	—	—
17	50 to 150 gm. of glucose daily parenterally	10 to 30 units regular insulin daily	—	—	Liver normal at autopsy	—

hours. During this interval the plasma chloride level fell to 507 mg per 100 cc, and the patient complained of abdominal cramps, which were relieved by the administration of 3 gm of sodium

mixture was given to prevent the unpleasant symptoms associated with hypochloremia. On the lower carbohydrate intake liver glycogen was depleted, and conditions more favorable to the development

of ketosis were provided. During the second period ketonemia was marked.

At this time no information is available regarding whether totally depancreatized human beings will eventually develop the degenerative changes associated with prolonged spontaneous diabetes, although atheromatosis and arteriosclerosis have been reported in depancreatized dogs.<sup>21</sup>

### Liver Changes

It has long been known that totally depancreatized dogs maintained on adequate diets and insulin cannot be kept in a state of health for long periods. After four to six weeks on such a regime the animals begin to show a decrease in glucose excretion, increased insulin sensitivity, hypolipemia and a loss of appetite with cachexia. The general condition progressively deteriorates and ends in death, usually within a few months. At autopsy a

in lecithin, it probably represents a true internal secretion of the pancreas.

Associated with the fatty changes in the liver is a gradual reduction in plasma lipoids that begins four or five weeks after pancreatectomy in dogs and falls to about 50 per cent of the normal level by the twentieth week after operation.<sup>32</sup>

Few observations are available concerning the plasma lipoids and liver function in totally depancreatized human beings. Plasma lipid studies have been reported in 5 of the 17 cases in the literature (Cases 2, 8, 13, 14 and 15 in Table 1). Of the cases in Table 1, Cases 2 and 15 showed normal plasma lipoids thirty-seven months and one month, respectively, after operation. In Case 8 the values of plasma lipoids slowly declined during the three and a half months of survival but were never abnormal. In Case 13 the plasma lipoids were normal seventy days after operation but were slightly below normal

TABLE 2 *Insulin Requirement in Patients Surviving Immediate Postoperative Period*

AUTHOR	AGE OF PATIENT	SEX	TIME OF SURVIVAL	DAILY FOOD INTAKE			DAILY INSULIN REQUIREMENT
				CARBO-HYDRATE	PROTEIN	FAT	
	yr		mo	gm	gm	gm	units
Priestly et al. <sup>1</sup>	49	F	37	243	94	70	30
McClure <sup>2</sup>	46	M	4				26-34
Brunschwig <sup>3</sup>	53	M	3½	401	102	11	40
Whipple <sup>13</sup>	26	F	12	300	70	75	30-80
Waugh et al. <sup>4</sup>	36	F	8	267	125	103	32
Dixon <sup>16</sup>	50	M	14	272	107	100	40
Clagett <sup>17</sup>	37	F	2½	250	75	101	38

majority of the animals, but not all, display a remarkable accumulation of fat in the liver, and the resulting impairment of liver function can be accurately estimated before death by the degree of retention of bromsulfalein.<sup>22</sup> Fisher<sup>23</sup> and Allan et al.<sup>24</sup> showed in 1924 that the addition of raw pancreas to the diet effectively prevented the changes in the liver and that the animals could be maintained in a state of health for long periods. Lecithin<sup>25, 26</sup> and later choline<sup>27, 28</sup> were found to prevent the deposition of fat in the liver when added to the diet in adequate quantities and also to cause the liver to return to normal after the condition had developed. More recently methionine has been shown to possess the same properties of prevention and cure.<sup>6, 29</sup>

In addition to the substances listed above, Dragstedt<sup>21, 30, 31</sup> has identified what he believes to be a second internal secretion of the pancreas, probably formed in the alpha cells, which has remarkable properties for preventing or curing the liver changes resulting from total pancreatectomy in dogs. This substance, which he terms "Lipocaic," is not present in the external secretion of the pancreas and has been prepared free of lecithin and practically free of choline. Since it has been found only in extracts of pancreas and not in extracts of other organs rich

on the hundred and twenty-third day. At the later examination the patient was jaundiced, and this fact may have played a part in lowering the values. In Case 14 a 100 per cent increase in plasma lipoids was found eight months after operation. The explanation of this is not clear, since at the same time the bromsulfalein retention was normal and exactly the opposite occurs after pancreatectomy in dogs.

The condition of the liver at autopsy has been described in 3 cases (Cases 1, 8 and 17 in Table 1). In 2 of these it was found to be normal fifteen days and eight days, respectively, after operation. In the other case the liver was described as fatty three and a half months after operation, but the cause of death was diabetic coma due to insulin withdrawal, which may have been responsible for the findings.

Bromsulfalein liver-function studies have been reported in 3 cases (Cases 2, 14 and 15 in Table 1) and were normal in all thirty-seven months, eight months and one month, respectively, after operation.

Although material concerning the effects of total pancreatectomy on the liver in man is scanty, it is evident from the discussion presented above that the gross fatty changes noted in depancreatized dogs have not been observed either clinically or at

autopsy. However, changes similar to those seen in the dog and responding to the administration of lipocain have been observed in spontaneous diabetes<sup>22</sup> and after destruction of the pancreas from repeated attacks of acute pancreatitis.<sup>20</sup> From these observations it is unlikely that the failure to observe in man the liver changes noted in the dog is due to a species immunity, although this factor must be considered, since it is well known that there is great variation in the severity of the diabetes and in the ability to form ketone bodies among different species of animals after depancreatization. It is more probable that the presence of choline and other lipotropic substances in the diet of man is sufficient to protect the liver.

### *Digestion and Absorption*

Experiences after ligation of the pancreatic ducts incident to partial pancreatectomy have led to conflicting reports on the effects of exclusion of the external secretion of the pancreas from the gastrointestinal tract.<sup>31-33</sup> Some patients develop bulky, frothy, foul-smelling stools, which contain large percentages of the ingested fat and nitrogen, whereas others remain relatively unaffected. Similar though less extensive loss of fat and nitrogen has been demonstrated after partial gastrectomy done for the relief of duodenal ulcer.<sup>37, 38</sup> Experimental work on dogs after complete pancreatectomy, the production of a complete pancreatic fistula or evulsion of the pancreatic ducts showed a marked loss of fat and carbohydrate in the feces.<sup>39, 40</sup> An increased excretion of fecal nitrogen was related to the increased bulk of the feces, which was less when diets rich in protein were employed. After evulsion of the pancreatic ducts there was a gradual failure of utilization of food, whereas the failure promptly followed total pancreatectomy or complete pancreatic fistula, leading to the conjecture that enzymes sufficient for the normal utilization of foodstuffs are absorbed from the obstructed pancreatic ducts. These experimental findings may explain the antithetical results noted in human patients after partial pancreatectomy.

Careful metabolic studies have been reported in only 2 cases of total pancreatectomy in man.<sup>4, 6, 10</sup> In these cases the stools were bulky, light, soft and usually formed. The average daily weight of the stool was two or three times that of normal subjects, largely owing to the excretion of large amounts of fat and protein. The average daily amount of fat eliminated in the stools was five to seven times the amount eliminated by normal persons, and the daily elimination of nitrogen was two and a half to seven times the normal amount.

Of the large amount of fat recovered in the stools, approximately a third was recovered as neutral fat, and the remainder as fatty acid, indicating that, in spite of the total absence of pancreatic enzymes, the splitting of fat was highly successful. The ad-

ministration of pancreatin, a commercial extract of pancreas, in doses of 15 gm per day caused an appreciable reduction in the loss of fat and nitrogen in the feces and a corresponding lowering of the bulk of the stools. On pancreatin therapy, however, there was no significant change in the percentage of nitrogen and fat in the stools, nor was there any change in the percentage of fat recovered as neutral fat and fatty acid. The administration of pancreatin was found to be highly useful in reducing the loss of calories in the stool. In one case 23.9 per cent of the ingested calories were lost in the stool during a test period on a carefully weighed diet.<sup>10</sup> During a second test period on the same diet, but with the addition of pancreatin, the caloric loss was reduced to 12.5 per cent. Although the nitrogen balance of this patient was positive even in the absence of pancreatin, the use of this drug made the maintenance of a positive nitrogen balance much easier.

### *Discussion*

In the present state of knowledge of the physiologic effects of total pancreatectomy in man the following points regarding the postoperative treatment of such cases may be emphasized.

The diabetes that follows total pancreatectomy is relatively mild and, at least in the early postoperative period, appears to be associated with an increased insulin sensitivity. Because of this, hypoglycemic reactions, which may be severe or even fatal should be carefully avoided. Early treatment of the diabetic state should be directed toward the prevention of ketosis rather than to the rigid control of blood sugar levels.

The fatty liver associated with total pancreatectomy in dogs has not been observed in man, but this is probably not a species immunity. Prevention of this disorder can probably be effected by a diet rich in choline. About 2 gm of choline daily is required to prevent fatty liver in pancreatectomized dogs. One egg yolk contains about 0.5 gm of choline, and liver and other glandular meats contain large amounts. In addition, choline chloride and methionine are available commercially and may be used to supplement the diet. In patients who survive for long periods, an occasional check on the level of plasma lipoids, as well as on the size of the liver as noted clinically, should give warning that fatty metamorphosis is taking place.

Because of the poor fat digestion in the total absence of pancreatic secretion, the stools tend to be bulky and frequent, and these changes are more marked the higher the fat content of the diet. For these reasons the postoperative diet should be low in fat, the caloric intake being made up with carbohydrates, which are well tolerated. In addition, pancreatin, in doses of 15 gm daily, should be administered to increase the absorption of fat and protein and to aid in the maintenance of nitrogen equilibrium.

## SUMMARY

A case of diffuse carcinoma of the pancreas treated by total pancreatectomy is presented, together with an analysis of similar cases reported in the literature.

The surgical mortality of total pancreatectomy is high, and the conditions demanding this type of procedure are not commonly encountered. With increasing experience the surgical mortality can probably be reduced to acceptable limits.

The physiologic changes that follow total pancreatectomy are discussed from the standpoint of the diabetic state, the liver changes and the loss of the external pancreatic secretions.

Suggestions for the postoperative care of patients after total pancreatectomy are presented.

## PULMONARY TULAREMIA IN MASSACHUSETTS

## Report of a Case Due to Tick Bites

WILLIAM E R GREER, M.D.\*

BOSTON

**T**ULAREMIA is a relatively rare disease in New England. The pulmonary form, which is even less common, occurs in Massachusetts, as in the case reported below. It is important to recognize the presence of *Pasteurella tularensis* and its many reservoirs and transmitting agents, for a specific treatment is now available in streptomycin. Otherwise, the pulmonary form is fatal in 40 to 50 per cent of cases. Because of this fact a case of the pulmonary form occurring in a resident of Cape Cod who showed excellent response to streptomycin therapy is reported below.

Tularemia has been reported in every New England state except Vermont.<sup>1</sup> Contact with *Past tularensis* has been noted through the following animals: rabbits, ground squirrels, cats, grouse, mink, sheep, swine and skunk.<sup>2</sup> The great reservoir of infection and the greatest source of human infection is the wild rabbit (jack cotton tail and snowshoe varieties), but owing to the agency of blood-sucking insects common to rabbits and man, cases also result from tick bites and fly bites.<sup>3</sup> The disease should be suspected more strongly in the months from March to October, the period of greatest tick activity. The disease is transmitted and maintained in animals by *Dermacentor andersoni* (the wood tick), *Chrysops discalis* (the horsefly), *Haemaphysalis leporis-palustris* (the rabbit tick) and *Dermacentor variabilis* (the American dog tick).<sup>4</sup> The fact that this disease may result from the bites of ticks or flies or from contamination of the skin or conjunctiva with the tissues or body fluids of infected rodents, flies or ticks is not fully appreciated.

## CASE REPORT

A 68-year-old retired physician, a resident of Duxbury, Massachusetts, was admitted to the hospital on June 9, 1947, because of fever of about 6 days' duration. The patient's residence was important in that he lived on Cape Cod in an area where ticks were especially plentiful in that year. The patient spent much of his time in the woods and fields and for the past month had noted frequent tick bites about his legs. The patient's dog, with which he was in frequent contact, was often infested with ticks, and the patient removed and crushed 10 to 15 ticks daily from the animal. About a week before admission the dog was said to have killed and eaten a rabbit after which the dog seemed sickly for several days. About 4 years previously a neighbor had been hospitalized for an "infected tick bite" and had noted fever and headache for approximately 2 weeks. In the week before admission the patient incurred a number of tick bites on his left leg and picked off a number of ticks each night. The illness began about 6 days before entry with the onset of moderate anorexia and a stinging pain in the left parietal region. These symptoms increased in intensity for the next

few days with the addition of gradually rising temperature to 104°F. Mild shaking chills were noted on the 3rd day of the illness. On the day before admission the temperature remained persistently elevated to 103 to 104°F and the patient showed much mental confusion. There had been no pulmonary symptoms, abdominal pain or change in bowel habits.

Physical examination revealed a well developed, well nourished, elderly man who was markedly confused, lethargic and irritable. There were multiple small (2 or 3 mm.) scabby lesions over the lateral area of the left leg, said to be tick bites; none were ulcerous or appeared infected. The tongue was mildly thickened and covered with a grayish coat. There were no palpable lymph nodes in any area of the body. Examination of the chest disclosed no abnormalities. Neurologic examination was negative. The liver or spleen could not be palpated, but liver dullness extended about two fingerbreadths below the right costal margin.

Examination of the blood revealed a white-cell count of 10,500 with 94 per cent neutrophils. The nonprotein nitrogen was 46 mg. per 100 cc. The agglutination test for undulant fever, the Weil-Felix reaction and agglutinations for *Proteus vulgaris* (strains X, X19 and X2) were negative. Agglutinations for *Escherichia typhosa*, *Salmonella paratyphi* (B), *S. choleraesuis* and *Shigella paradyenteriae* (Sonne and Flexner) were also negative. The heterophil antibody test was within normal limits, and the test for cold agglutinins was negative. Serum sent to the United States Public Health Service for agglutination for *Past tularensis* was reported as negative.

The temperature remained at about 104°F and the pulse remained above 100 for the first 24 hours. The patient was nauseated and vomited several times. He complained of severe frontal headache and was apathetic and mentally confused, but he demonstrated no additional physical signs. Lumbar puncture showed the cerebrospinal fluid to be within normal limits. On the following day the temperature ranged between 102 and 104°F, and the pulse between 90 and 100. The patient still exhibited no pulmonary symptoms, but physical examination revealed dullness in percussion, decreased breath sounds and a few coarse crackling rales over the left base posteriorly. X-ray examination on the following day showed an area of more or less homogeneous increased density in the left lower lung field. There was slight infiltration at both hilum. The appearance was that of pneumonia. The patient was started on penicillin therapy with no beneficial effects and with a temperature consistently elevated to 103 to 104°F, and became more lethargic, apathetic and mentally confused. A repeated cerebrospinal fluid examination was within normal limits. Streptomycin therapy in a dosage of 0.25 gm. intramuscularly every 3 hours was instituted on June 12, and after the patient had received 2 gm. for about 24 hours the temperature and pulse began to fall. The temperature reached normal on June 14 after the patient had received about 4.25 gm. of streptomycin. There was striking improvement of the symptoms of restlessness, irritability and mental confusion, and the patient stated that the severe headache had gone. The white-cell count decreased by 1,000 daily for 5 days, but the differential count consistently showed over 90 per cent of the neutrophil series. Numerous blood cultures demonstrated no growths. Except for a rise in temperature to about 100°F on June 14 and 15 the course of the disease was uneventful, and the temperature and pulse were within normal limits from June 14 to discharge on June 28. The patient had no recollection of the mental confusion and irritability.

The clinical course is demonstrated in Figure 1.

Serum sent to the United States Public Health Service on June 19 was reported as showing agglutination for *Past tularensis* through a dilution of 1:640, agglutination for *Brucella abortus* through a dilution of 1:10 and agglutination

\*Asst. prof. in medicine, Boston University School of Medicine; resident in medicine, Massachusetts Memorial Hospitals (Private Pavilion).

for *Proteus vulgaris* (strain X19) through a dilution of 1 20 This substantiated the diagnosis of tularemia of the typhoidal type

The pneumonia began to show signs of resolution on June 21, and the patient exhibited rapid improvement until discharge He wished to continue convalescence at home and to be followed by his physician X-ray study of the chest on June 25 demonstrated that consolidation was still present in the left lower lobe There was slight radiolucency medially, suggesting beginning resolution

### DISCUSSION

The public-health aspects presented by this case are important when it is realized that ticks represent a permanent reservoir of possible infection The

FIGURE 1

female can transmit the organism through the egg to the young, who then harbor them throughout their life.<sup>6</sup> Tularemia may simulate many diseases, such as meningitis, typhoid fever, Rocky Mountain spotted fever, atypical pneumonia, undulant fever and infectious mononucleosis. Owing to its variety it is frequently misdiagnosed as typhoid fever or pneumonia, so that it is essential to think of the disease in differential diagnosis. In Alberta, Canada, physicians include *Past tularensis* as an antigen in routine agglutination tests for typhoid and related organisms, and by this means a small number of cases have been found that might have been missed.<sup>2</sup>

Typhoidal tularemia comprises about 5 per cent of cases of tularemia, and both primary lesions and lymphadenitis are absent.<sup>7</sup> Instead, there is a general systemic infection in which fever and prostration are the outstanding symptoms. In the series studied by Warring and Ruffin<sup>1</sup> it was noted that delirium followed by drowsiness was most marked in the pulmonic type of the disease. In the more

serious of these cases definite areas of consolidation involving one or several lobes appeared. Resolution of the pneumonia began in the third week and was very slow, requiring from five weeks to six months for completion. In a series reported by Francis,<sup>3</sup> a bronchopneumonia type of lesion was the terminal condition in 5 cases, and a lobar-pneumonia type terminated fatally in 2 cases.

In fatal tularemia the most frequent pulmonary lesion is a pneumonia that is basically nodular or confluent nodular in character — sometimes lobar in extent — and involves one to all lobes.<sup>8</sup> The exudate is primarily monocytic and always shows more or less necrosis. In the central portions the septums are usually necrotic, with collagenous, reticular and elastic stroma persisting in considerable measure. Gram-positive cocci are often found in purulent exudates, usually copious. Delicately fibrillar, fibrinous exudates may be identified in some alveoli. The alveolar septums are congested in many cases, both in pneumonic areas and elsewhere. Serous exudation in the other congested areas is common. Vessels frequently show proliferative intimal reactions associated with mononuclear-cell infiltration and perhaps necrosis and thrombosis. The pleura shows fibrinous, fibrinocellular and fibrocaseous exudation in a number of cases.

### SUMMARY

A case of the pulmonary form of tularemia occurring in a resident of Massachusetts and successfully treated with streptomycin therapy is reported.

It is important to recognize the possibility of *Pasteurella tularensis* in the pulmonary form, for this disease is easily confused with others, and a specific treatment is now provided by streptomycin.

Owing to the agency of blood-sucking insects common to wild animals and to man, other cases may result from tick bites or fly bites. Ticks are reported to have shown a decided increase in 1947 in the Cape Cod region and have been noted north of Boston.

This was the first proved case of tularemia reported to the Massachusetts Department of Public Health for 1947. Seven cases in all were reported during 1947 — an unusually high incidence of the disease.

## PRESACRAL NEURECTOMY FOR DYSMENORRHEA\*

FRANCIS M. INGERSOLL, M.D.,† AND JOE V. MEIGS, M.D.‡

BOSTON

THIS paper deals with a series of presacral neurectomies performed for relief of dysmenorrhea. A total of 111 operations have been done at the Massachusetts General Hospital and the Palmer Memorial Hospital from 1930-1946. In most cases the neurectomy was combined with dilatation and curettage, a suspension and any other necessary pelvic surgery that the gynecologic situation demanded. These 111 cases can be divided into a group with essential dysmenorrhea and a group with acquired dysmenorrhea. The patients in the former group had severe crampy pain starting shortly after the menarche, with painful menstruation that

relief in 52.6 per cent and partial relief in 21 per cent of cases, and in 26.4 per cent the operation failed, the causes of the dysmenorrhea in this group are presented in Table 2.

In this series there were no deaths. There were only 2 serious postoperative complications severe

severely upset their social and economic life, physical examination was negative. The patients with acquired dysmenorrhea had obvious pathologic processes to explain the painful periods. Table 1 gives the results in both groups.

Evaluation of results from the operation were based on a personal follow-up study in the majority of cases and by a follow-up letter in a few. There was little difference in early and late follow-up. If the operation was judged successful at six months the same report was received years later except in 2 cases, which are discussed below. The results were divided into patients with complete relief, those with equivocal or partial relief and those on whom the operation failed.

Complete relief was obtained in 81 per cent and partial relief in 4.5 per cent of patients with essential dysmenorrhea, and there were failures in 12, or 14.5 per cent. In contrast, in the group with acquired dysmenorrhea, in which there was an obvious cause for the pain, presacral neurectomy in addition to other gynecologic procedures gave complete

small-bowel obstructions due to adhesions to the incision in the posterior peritoneum. Lysis of the adhesions was necessary after the intestinal obstruction had been relieved by Miller-Abbott tube. These complications of intestinal obstruction occurred in patients with acquired dysmenorrhea, both of whom had pelvic inflammatory disease.

There was only 1 serious operative complication, a severe hemorrhage from the left common iliac vein when a small branch was avulsed. The rent in the vein was closed, arterial silk being used.

## CAUSES OF FAILURE

Previous reports have adequately demonstrated the efficacy of presacral neurectomy in essential dysmenorrhea, which is now a standard operative procedure in pelvic surgery. However, Tucker<sup>1</sup> reports failures in 11 per cent of cases, Fontaine and Herman<sup>2</sup> in 13 per cent, and Meigs<sup>3</sup> in 15 per cent. Most authors have had about this same percentage of failures. And that is the group upon whom attention should be focused. Of course, the surgeon can calmly accept his 10 to 15 per cent failures and pay no attention to them, or label the patients psychoneurotics and send them to a psychiatrist after operation. In this study major interest was focused on the failures to determine if any measures could be taken to prevent failures in the future. Of great importance is the fact that the cause of dysmenorrhea is not actually known. Anatomic, functional and hormonal studies have not definitely proved what causes crampy pains with menstruation. Rational therapy without knowledge of the etiology is impossible. It is known that these patients are usually sensitive and emotional. Haman<sup>4</sup> has ac-

curately shown that the pain sensitivity of the patient with dysmenorrhea is low, and the psychiatrists have long emphasized the role of the emotional background of women in this problem. It is our belief that all other means of curing dysmenorrhea should be tried before a presacral neurectomy is performed.

An analysis of the 12 cases in which presacral neurectomy failed to afford relief of essential dysmenorrhea showed that the three possible causes for the failure were psychoneurosis (3 cases), regeneration of the sympathetic nerves (2 cases) and incomplete sympathectomy (7 cases).

The first group comprises three cases judged to be psychoneurotic and emphasizes the importance of the careful choice of the patients. Care was taken in selecting these patients for presacral neurectomy, but the patients who were psychoneurotic, and possibly others in whom the operation failed, were nevertheless subjected to operation. The number of patients with dysmenorrhea who were not judged fit candidates for presacral neurectomy cannot be

If this test is carried out with inhibition of ovulation and the bleeding is still associated with pain, it is safe to assume that the patient has pain on experiencing any vaginal bleeding, and a psychiatrist rather than a surgeon should be consulted. This test is now carried out on all patients who have severe dysmenorrhea, and only those who have complete relief of pain after the estrogen withdrawal are operated upon.

Thirty-five patients were given estrogens and subsequently operated upon (Table 3). The significance of the test is illustrated by the patients who were not relieved of dysmenorrhea after the estrogens and on whom presacral neurectomy was nevertheless performed, resulting in failure. Two of these patients were seen by psychiatrists, and study showed them to be overly sensitive and their dysmenorrhea to be associated with intense emotional difficulties. The third patient had no relief preoperatively with estrogens, and operation was a failure. She too was sensitive, but it was difficult to prove any clean-cut psychoneurotic element in the dysmenorrhea. We believe that this test proves that if the estrogen-withdrawal bleeding is painful presacral neurectomy should not be done.

The second possible cause of failure of this operation is regeneration of the sympathetic nerves. Two cases in which presacral neurectomy failed may be accounted for on this basis. This problem of regeneration of the sympathetic nerves has plagued surgeons interested in other types of sympathectomy. This has been especially true in the dorsal sympathectomies for Raynaud's disease. The early operations done at the Massachusetts General Hospital successfully denervated the upper extremities, but within six months to a year the disease recurred. Sweating and skin-temperature tests showed that the sympathetic nerves had regenerated. Reoperation demonstrated the regenerated nerves. Smithwick<sup>6</sup> circumvented this regeneration in dorsal sympathectomies by attaching a silk cylinder around the cut nerve ends. In splanchnic resections for relief of abdominal pain regeneration also occurs, and relief by sympathectomy may be of short duration. Little mention has been made of this possibility after presacral neurectomy. Regeneration may account for 2 of the failures in our series. Both were considered successful cases with satisfactory relief of pain at their six-month postoperative visits. However, when this follow-up study was undertaken and a questionnaire sent out, 1 patient was three years after operation and the other seven, and both called the operation a failure and said that the dysmenorrhea had returned. Neither permitted reoperation to determine if regeneration had occurred, but that seems to be the best explanation. The infrequency of regeneration after this type of sympathectomy may be due to the fact that a long segment of nerve is removed, which so widely separates the nerve ends that they never rejoin. A reliable

given, since there is no way in either ward or private practice to obtain the records of all patients with dysmenorrhea. Others have attempted to eliminate the psychoneurotic patients by various methods. Flothow<sup>6</sup> advocated a block of the second and third lumbar segments and also of the superior hypogastric plexus with 2 per cent procaine while the patient was experiencing dysmenorrhea, if relief of pain was produced, presacral neurectomy was advised. He cites an example of a patient with dysmenorrhea who was not relieved by his injection or by spinal anesthesia effective to the nipple line, she was not operated upon. Because of difficulty in obtaining hospital beds we have not used this injection method but have attempted to eliminate the psychoneurotic patients by another test.

This test consists of preventing ovulation by the use of estrogen and then stopping the estrogen and allowing the patients to have withdrawal bleeding. Estrogen-withdrawal bleeding or anovulatory bleeding is painless in the normal, healthy female. A variety of estrogens have been used to stop ovulation. For example, diethylstilbestrol (1 mg daily) may be given for twenty days, starting on the first day of menstruation, ovulation is prevented, and two to eight days after the stilbestrol is stopped withdrawal bleeding occurs and the patient has a painless period.

test to determine the sympathetic supply to the uterus would be of help in this group.

The third possible cause of the failures is an inadequate sympathetomy. Seven cases were so classified because there was no other explanation. By history the dysmenorrhea was essential or primary. In 5 patients the estrogen test before operation completely relieved the pain, and yet presacral neurectomy was a failure. Sympathetic fibers may be missed at two places: the branches from the fourth lumbar ganglion to the presacral plexus often come from beneath the arteries rather than over the anterior surface, and these branches may be missed, more important is the chance of missing a large trunk that goes downward close to the inferior mesenteric and superior hemorrhoidal vessels. Elaut,<sup>7</sup> in a dissection of this area found that in only 25 per cent of the cases is the presacral nerve a distinct, single nerve. In 58 per cent there is a plexus lying between the common iliac arteries; in 16 per cent there are two parallel nerves, and in 2 per cent the nerve is arch shaped. In the last group the nerve may remain close to the inferior mesenteric vessels, and if the sigmoid is in a fairly free mesentery the presacral nerve may be retracted far laterally during the dissection and therefore missed. This anatomic variation may well account for some of the failures of this operation.

#### PREGNANCY FOLLOWING PRESACRAL NEURECTOMY

Follow-up study on this group of 111 cases revealed the fact that 24 patients have had children since presacral neurectomy was performed. Since this operation successfully relieves menstrual cramps we were interested to see what effect the operation had upon first-stage labor pains. Of these 24 patients 8, or 33.3 per cent, experienced no severe cramps with uterine contractions and required no medication. These women and their obstetricians all commented on the lack of pain with labor. Several did complain of low back pain, and all noted the alternate hardness and softness of the uterus. Several patients experienced sensations other than pain with their contraction, such as a tingling sensation at the base of the spine. Two patients complained of discomfort in the rectum, and 1 of intestinal cramps. Two primiparas were delivered without obstetric assistance, since they had not thought that they were in labor until the vertex encountered the perineum. All the patients experienced pain with passage of the baby through the perineum, although this occurred so rapidly that post partum the patient complained of only one brief episode of pain. The force of uterine contractions was normal, and the obstetricians remarked that the labor seemed shorter than that of the average primiparous delivery. Of the 8 women with painless deliveries 6 had essential dysmenorrhea, and 2 had acquired dysmenorrhea due to endometriosis. Seven of the 8 had had complete relief of the dysmenorrhea by

presacral neurectomy. In these 8 cases with painless deliveries the resection of the presacral plexus must have denervated the fundus of the uterus completely. The backaches described are probably due to dilatation of the cervix. Patients, therefore, who have had this operation should be warned that the first stage of labor may be painless and that the physician in charge should be notified when the uterus begins to contract regularly and forcefully.

#### INNERVATION OF THE UTERINE FUNDUS AND CERVIX

Follow-up study also revealed the fact that although the relief of the crampy pains of menstruation was quite successful, 7 patients with essential dysmenorrhea continued to have backache with the periods. The backaches were not incapacitating. This fact that low abdominal cramps were relieved by presacral neurectomy and yet that the backache persisted aroused our interest in the innervation of the fundus and cervix. Pain from the uterus must pass upward in afferent fibers through the presacral plexus to reach the spinal cord. As with other visceral pain the actual pain felt by the patient is referred out along the sensory roots at the same level that the sympathetic fibers reach the cord. Theobald<sup>8</sup> believed that stimulation of the autonomic-nerve endings in the cervix caused a referred pain in the area of skin supplied by branches of the first lumbar nerve and that this pain should be abolished by local anesthesia to the skin area. Labor pain was also interpreted as being a viscerosensory, referred pain. Interruption of the presacral plexus by presacral neurectomy breaks this referred-pain arc. The work of Cleland<sup>9</sup> indicates that the afferent nerves from the fundus reach the cord at the level of the eleventh and twelfth dorsal segments. He found that nupercaine paravertebral block at this level relieved the pain of uterine contractions of women in active labor. Hingson<sup>10</sup> has confirmed this observation since he observed in 3000 cases that caudal anesthesia relieved the abdominal cramps of labor if the anesthetic included the eleventh dorsal segment.

In some women all the afferent fibers may go upward and through the presacral plexus from the cervix to the first dorsal and from the fundus to the eleventh and twelfth dorsal segments. However, since backache is often unrelieved by presacral neurectomy, the afferent nerve supply from the lower part of the uterus may pass outward through some other afferents. Anatomic dissections have shown that the parasympathetic supply to the uterus is from the second, third and fourth sacral segments. This fact may provide a good explanation of why the backaches associated with menstruation are unrelieved by presacral neurectomy and may also account for the backache that the women in labor had after presacral neurectomy, even though they experienced no cramps in 8 out of 24 cases.

Another bit of evidence that may point to variation in the innervation of fundus and cervix was presented by Meigs,<sup>3</sup> who did endometrial biopsies on 2 patients after presacral neurectomy and found that the passage of the curette through the internal os of the cervix caused backache but that scraping of the endometrial cavity caused no pain. He concluded that the cervix had not been denervated. Further studies are under way more accurately to map out the pathways from uterus and cervix to the central nervous system.

#### ENDOMETRIOSIS AND DYSMENORRHEA

We have been interested in searching for tiny areas of endometriosis in these patients with dysmenorrhea. Of the 89 patients with typical histories of essential dysmenorrhea 10 had tiny areas of endometriosis removed from the uterosacral ligaments or from the anterior surface of the uterus near the junction of the uterus and bladder. Endometriosis of this magnitude was only an incidental finding at operation and was not considered as an etiologic factor in the dysmenorrhea. Nine of these patients had complete relief of cramps after presacral neurectomy. In only 1 case to date has the endometriosis progressed. This patient had 90 per cent relief of cramps four years later but complained of sharp pain on the left side. Fixation of the left ovary suggested endometriosis. This observation of endometriosis in 11 per cent of patients with essential dysmenorrhea, whose average age was twenty-four years, makes it apparent that endometriosis may start at an early age. Whether women with essential dysmenorrhea are prone to develop endometriosis has not been ascertained from this study.

#### DYSMENORRHEA FOLLOWING APPENDECTOMY

Included among the patients with acquired dysmenorrhea were 3 whose painful menstruation dated from an appendectomy. Tucker<sup>1</sup> had a similar group of patients, and presacral neurectomy for the dysmenorrhea relieved the cramps. No obvious cause was found at operation on these patients. The histories were very similar. The first patient had no pain with the periods, which had begun at the age of twelve, until she had a normal appendix removed at the age of nineteen. The periods grew steadily more painful postoperatively until a dilatation and curettage and presacral neurectomy four years later. No cause for the pain was found at laparotomy, and presacral neurectomy gave complete relief. In the second patient the periods had started at the age

of fourteen and had been painless until appendectomy at the age of twenty. Thereafter severe cramps began two days before each period and continued for the first two days of the period until relieved by presacral neurectomy two and a half years later. No cause for the cramps was found at operation. In the third patient the periods had begun at the age of thirteen and had been painless until an appendectomy was done for chronic appendicitis at the age of twenty-two. After the operation severe cramps developed, starting one day before the onset of flow and lasting two or three days without let-up. At laparotomy six years later, a small endometrioma was found. The cramps were 90 per cent relieved by presacral neurectomy and resection of an endometrioma of the right ovary. A graduate nurse from this hospital gives exactly the same history of onset after appendectomy, having been free of pain prior to operation. This girl has refused presacral neurectomy. These cases are summarized to draw attention to the phenomenon of pain beginning after appendectomy. Fortunately, presacral neurectomy succeeded in relieving the dysmenorrhea.

#### SUMMARY

A series of 111 cases of presacral neurectomy for dysmenorrhea are reviewed. Complete relief was obtained in 81 per cent of cases of essential and 52.6 per cent of acquired dysmenorrhea. There were 12 failures after presacral neurectomy for essential dysmenorrhea. These failures are accounted for on the basis of either regeneration of sympathetic nerves, incomplete operation or dysmenorrhea as a manifestation of a psychoneurosis. Twenty-four women had babies postoperatively, labor was painless for 33.3 per cent.

## PRIMARY FRIEDLANDER-BACILLUS PERITONITIS\*

## Report of a Case

MELVIN P. OSBORNE, M.D.†

BOSTON

**PRIMARY** unexplained infection of the peritoneum by the Friedländer bacillus (*Klebsiella pneumoniae*) is a condition of evident rarity. The case reported below (the second in the medical literature) describes a disease that is a distinct though little known clinical entity. Additional reports will aid in delineating possible similarity to the better known idiopathic pneumococcal and streptococcal peritonitides of infants and children.

## CASE REPORT

E. I., an 8-year-old girl of Irish descent was referred to the hospital in April, 1943, by her family physician with the diagnosis of appendicitis with perforation. The immediate history dated to 4 days before admission when she had complained of abdominal cramps and had vomited and retired to bed. There had been no stool for 3 days the appetite had been very poor until the morning of admission and since then the patient had eaten nothing. The abdominal cramps diminished somewhat after the 1st day but on the day of admission returned with marked severity throughout the entire abdomen and the child vomited several times. An enema was given on the afternoon before admission with slight relief from pain after expulsion of a small amount of gas. There had been some burning pain with urination on the day of admission.

The past history indicated no similar previous illnesses. The patient had been suffering from a fairly severe upper respiratory infection during the 2 weeks prior to admission. No previous symptoms could be referred to the gastrointestinal tract, urinary tract or gynecologic disorder. The patient had had measles and chicken pox in earlier childhood. A younger sister and the parents had been well during the period of the patient's illness. The remainder of the family history was noncontributory.

Physical examination showed the patient to be acutely sick, pale, listless and poorly oriented and breathing rapidly and complaining of generalized abdominal pain. The head was essentially normal. There was a very slight injection of the oropharynx the tonsils were not remarkable. A few small, slightly tender lymph nodes were palpable in the neck axillae and groins. The chest was clear resonant and symmetrical and normal by roentgenogram. The abdomen was distended, tense and tender in all quadrants, especially the lower. No masses were palpable. There was tympany throughout. No peristalsis was audible. Rectal examination demonstrated tenderness in all directions and withdrawal of the examining finger was followed by expulsion of gas and enema fluid.

The temperature was 103.8°F by rectum the pulse 140 and the respirations 28.

The white-cell count was 3600 with 64 per cent neutrophils, and when repeated in 2 hours, 3200 with 56 per cent neutrophils. The hemoglobin was 68 per cent (9.5 gm per 100 cc. of blood). Clear bile-stained vomitus was guaiac negative. The urine was straw colored clear and acid with a specific gravity of 1.014 no albumin or sugar and no remarkable sediment.

A diagnosis of generalized peritonitis due to a perforated appendix or idiopathic pneumococcal infection was considered.

Immediate treatment consisted of placing the patient in an oxygen tent in restraints and allowing nothing by mouth

except cracked ice. Codeine phosphate (0.06 gm.) and sodium luminal (0.06 gm.) were given subcutaneously as often as needed for pain and restlessness. A Levine tube was passed into the stomach which was emptied of a small amount of fluid and was left for open dependent drainage. The patient was immediately given 1500 cc. of 10 per cent dextrose in physiologic saline solution with 2 gm. of sulfanilamide in solution as prontosil and this was followed with 300 cc. of cross matched citrated whole blood on the evening of admission. A Miller-Abbott tube (size No. 12 Fr.) was passed 75 cm. and was to be advanced on the following morning the patient pulled the tube out, and it was not reinserted.

On the 1st hospital day the patient was listless and less well oriented than on admission and appeared to be in poor condition. A repeated examination of the blood showed 8.5 gm. hemoglobin per 100 cc. and a white-cell count of 5100 with 54 per cent neutrophils. Operation under local anesthesia for drainage of pus from the lower abdomen and implantation of sulfanilamide was elected. A small right lower-quadrant, muscle splitting incision was made and approximately 500 cc. of yellow acid-smelling fluid, of the consistency of thick broth was expelled from the lower abdomen as though under pressure. A large rubber tube was inserted in the pelvis and 8 gm. of crystalline sulfanilamide was implanted in the lower abdomen through the wound. This procedure was tolerated well.

The patient was treated on this and the 3 succeeding hospital days with continuous daily infusions of 2500 cc. of 10 per cent dextrose in physiologic saline solution in addition to the infusion of 250 cc. of cross matched citrated whole blood every 12 hours. The sulfanilamide level on the day after operation was 11.4 mg per 100 cc. and thereafter sodium sulfadiazine in the continuous infusion was given in a dosage of 3 gm. per day. Sulfadiazine levels between 10.4 and 22 mg per 100 cc. were subsequently recorded. The carbon dioxide combining power varied between 41.6 and 62 vol. per cent and the urea nitrogen between 6.5 and 8.6 gm per 100 cc. The hematocrit on the 3rd hospital day was 38 per cent. Hemoglobin determinations on the 1st, 2nd and 3rd days were 8.5, 10.5 and 10 gm per 100 cc. of blood. The white-cell count mounted to 16,700, with 88 per cent neutrophils, by the 2nd hospital day but fell to 10,400 with 68 per cent neutrophils on the 3rd day. The urine output was estimated to be satisfactory with at least 500 cc. each day. A culture of pus from the abdominal cavity at the time of operation grew out Friedländer bacillus in pure culture. A blood culture on the day of death was sterile.

Although some clinical improvement was noted in the hours immediately after operation, the patient's condition became progressively worse, and the temperature of 102°F mounted to 104°F 6 hours before death. The pulse mounted progressively to 176, and the respirations became more rapid shallow and thoracic in character, remaining between 35 and 40 during the last 2 days. Signs of atelectasis and scattered coarse rales were noted during the last 2 days and on the 4th hospital day the patient became comatose, aspirated vomitus and expired.

**Autopsy.** Post mortem examination performed by Dr. Walter W. Brandes revealed a well developed and well nourished child weighing 25 kg. There was moderate cyanosis of the face and fingertips. The abdomen was moderately distended and a recent 8-cm long McBurney incision was present.

The peritoneal cavity contained 1000 cc. of turbid fluid with numerous soft, gray masses of exudate rich in fibrin. The peritoneal surfaces were hyperemic, and thick deposits of this exudate were present over them as well as over the upper surface of the liver. The appendix was also partly

\*From the Surgical Service (First Division) Roosevelt Hospital New York City.

†Assistant resident in surgery, Fifth Surgical Service, Boston City Hospital formerly house officer, Roosevelt Hospital.

covered. No evidence of rupture or perforation of any viscus was found.

The pelvic organs showed peritoneal hyperemia and depositions of fibrinous exudate. The fallopian tubes were patent, and their lumens were free of exudate. The cavity of the uterus disclosed no evidence of inflammation. The ovaries were not enlarged.

Other organs demonstrated changes associated with marked inflammatory reactions. There was acute splenic swelling, parenchymatous degeneration of the liver and kidneys and passive hyperemia. Medullary portions of the adrenal glands were softened. The mesenteric lymph nodes were moderately swollen, soft and hyperemic. The small bowel presented only the serosal change mentioned. The mucosa of the cecum and ascending colon was noticeably swollen, it was soft, pale, and grossly edematous. There was no ulceration. The rectum was not noticeably altered. The pancreas was normal, and the gall bladder and bile ducts were not remarkable.

Examination of the pleural cavities revealed a small amount of fibrin present on the diaphragmatic surfaces. The thymus, mediastinum, great vessels, pericardium and heart were not remarkable. The trachea and major bronchi contained a small amount of gastric contents. Their mucosa was bluish red. The lungs revealed no gross evidence of pneumonia. They presented peripheral collapse, which was most noticeable in the lower lobes, more on the left side, involving two thirds of the left lower lobe.

Microscopical changes were those of an acute fibropurulent inflammation of the peritoneal surfaces. The exudate was composed of fibrin and leukocytes, fibrin predominated. Some of the polymorphonuclear cells were swollen and vacuolated. The subserosal layer of the peritoneal surfaces revealed marked hyperemia and edema, the edema sometimes extending to the submucosa of the bowel. There was no evidence of primary inflammation of the appendix, uterus, fallopian tubes or ovaries or of the gall bladder.

Cultures of the peritoneal exudate demonstrated a pure growth of Friedländer bacillus, contents of the lumen of the terminal ileum revealed the presence of this organism along with *Escherichia coli* and an unidentified member of the Clostridium group. A throat culture failed to demonstrate Friedländer bacilli.

Morphology of the cultures, cultural characteristics and morphology of the organism were those of Friedländer bacillus. Intraperitoneal mouse inoculations resulted in death after 12 hours, with demonstration of the organism in the peritoneal smear. Serologic typing of the organism (Julianella) was not performed.

### DISCUSSION

The post-mortem examination failed to reveal the portal of entry of the infection or any primary site. Changes in the bowel, including the marked edema of the proximal colon, were, in all likelihood, secondary to the peritonitis. The presence of the infecting organism in the bowel lumen suggests that site as its source. In some unexplained manner the peritoneum became infected. Review of the literature disclosed a single case of probable primary peritonitis due to Friedländer bacillus reported in England by Cook<sup>1</sup> in 1931. As in the case presented above, the patient was a young girl (nine years old), she had an acute tonsillitis with exudate, and redness of the vagina, as well as generalized peritonitis when she was first seen five hours before death. This patient was treated by drainage of the lower abdomen performed under local anesthesia. Pus was described as dark and foul. Details of autopsy examination offered were throat and peritoneal culture (showing *K. pneumoniae*) and a description of a generalized peritonitis similar to that in the case presented above.

McDonald and Klingon<sup>2</sup> reported a case of peritoneal infection as "primary peritonitis caused by Friedländer's bacillus" in 1946, and considered it to be the first of such reports, apparently overlooking Cook's case. A review of their report leads to the conclusion that their case is not acceptable as a primary peritonitis of the etiology stated. The patient was a forty-seven-year-old man with a medically complicated past history and a recent history suggestive of a perforative lesion in the gastrointestinal tract. The patient was operated upon a few hours after the onset of an abdominal crisis, the culture of pus grew out not only a Friedländer bacillus but also beta-hemolytic anaerobic streptococci. The presence of a mixed bacterial infection, as well as certain other inconsistencies in the diagnosis, suggests that the case of Cook and the one reported above actually represent the only reported primary idiopathic infections of the peritoneum by the Friedländer bacillus.

### TREATMENT

Aside from the merits of drainage vs nondrainage and intraperitoneal use of sulfonamides, rational therapy for this condition with means now at hand must be predicated on early diagnosis and the most likely antibacterial agents used. The technic reported by Ladd and Gross et al. as used at the Children's Hospital, Boston, with diagnostic smear of peritoneal exudate obtained by early laparotomy, would accomplish differentiation of the Friedländer bacillus from the streptococcus, pneumococcus and the mixed infection of fecal peritonitis. The Friedländer bacillus is easily recognized as an encapsulated, short, plump, gram-negative rod and is present, in large numbers in exudates of peritoneal infection so caused. Characteristic encapsulation is striking in these smears and is easily seen with ordinary aniline (dye) stains.

Studies and reports in recent years have indicated that sulfadiazine is probably the most effective sulfonamide drug for use against the Friedländer bacillus. Sesler and Schmidt<sup>3</sup> have shown clearly that this is true both in vitro and in animal experiments, although the variation in reaction of different strains of the organism is emphasized. Ransmeier and Major<sup>4</sup> assembled comparative statistics of mortality to show that sulfadiazine improves the outlook in the highly fatal Friedländer meningitides. Heilman<sup>5</sup> and others have shown that streptomycin may be more effective than any other antibacterial agent.

Penicillin is not effective in physiologically feasible concentration. However, Heilman and others found such variation in sensitivity to streptomycin (four thousand times the original concentrations in vitro) of different strains that one must conclude that some cases cannot be benefited by streptomycin administration. When possible, preliminary assay of the effect of either sulfadiazine or streptomycin in vitro

would aid in anticipating the most successful treatment. Serologic and bacteriologic classification of the organism is of no value, since there is no correlation between type and either sensitivity to sulfadiazine and streptomycin or virulence and occurrence as a pathogen. Organisms are most often Julianelle Type A, but virulent infections are also caused by types B and C and those of Group X.

### BACTERIOLOGY

The Friedländer bacillus is grossly related to the coliform group. It is known to be a common organism of the bacteriologic flora of the intestinal tract. Kendall,<sup>6</sup> whose study seems to have included *Aerobacter aerogenes* as well, found that these organisms were common in the intestines of infants but not in those of adults, whereas Dudgeon<sup>7</sup> cultured the organisms in the feces of 55 per cent of a large group of patients, most of whom had some lesion or disease of the oropharynx or of the intestinal tract. Baehr, Schwartzman and Greenspan<sup>8</sup> state that it is a more frequent inhabitant of the intestine than elsewhere and is rare as a primary pathogen in the respiratory tract, where it usually appears as a secondary invader. Most textbooks of bacteriology state that this organism is found chiefly in the respiratory tract in man. The Mt Sinai workers, however, report a unique and significant study of 61 cases of peritonitis caused by this organism alone or in conjunction with other organisms, in all these cases the portal of entry was demonstrated (mostly perforated appendix or bowel). The authors further described abdominal infection from liver abscess and biliary-tract, urinary-tract and pelvic infection, so that of 198 consecutive cases reviewed, 163 infections due to the Friedländer bacillus were present in the abdomen, pelvis or urinary tract. This report has stimulated comment<sup>9</sup> and greatly clarifies the understanding of the pathogenesis of infections due to the Friedländer bacillus.

After Friedländer<sup>11</sup> described the organism that bears his name as the virus causing lobar pneumonia (from post-mortem lung cultures in 8 cases) and designed it as "*Klebsiella pneumoniae*," the error of his conclusion was soon demonstrated by description of the pneumococcus as the far more common pathogen in such cases. However, even now the term "pneumobacillus" is a common synonym for the official (Bergey) *K. pneumoniae*. It has been suggested that the long-delayed recognition of the true natural occurrence of the Friedländer bacillus as a pathogen may be due in part to cultural and morphologic similarity to the colon bacillus, because of which in modern rapid hospital bacteriology the Friedländer bacillus is often reported as *Esch. coli*, and to the larger attention accorded culture and other bacteriologic study on medical wards (and in cases of chest infection) than on surgical patients (with perforative lesions of the gastrointestinal tract).

In this connection, the excellent studies of Ostermann and Rettger<sup>12,13</sup> on comparison of the organisms of the Friedländer and coli-aerogenes groups are cited. These authors indicate that, whereas there may occasionally be erroneous identification by ordinary biochemical reactions and cultural characteristics (in particular when virulent nonencapsulated forms of Friedländer and *Aerobacter* organisms or colon bacilli that are encapsulated are encountered), no valid criteria exist for the differentiation of the organisms that can be applied consistently to all cases. The authors state that there has been a tendency to rely on the origin of a culture as a material aid in its identification and point out that in their study, cultures of *Esch. coli* and *A. aerogenes*, as well as the Friedländer bacillus, came from similar and diverse natural sources. They consider that further study by serologic means will provide a more complete explanation of interrelations.

Examination of the bacteriology in reports cited reveals that in Cook's case, only a statement that the cultures showed a Friedländer bacillus is offered, in the case reported above, the morphology, mouse virulence and biochemical characteristics (admittedly variable) were the basis for identification, and in the series of Baehr, Schwartzman and Greenspan, the criteria were "Gram negative bacilli showing well defined capsule and typical 'gum drop' and stringy colonies on solid media were considered to belong to the *B. friedländer* group, provided these characteristics persisted for at least three to four passages through artificial media." Thus, the certainty that these authors were not in some cases dealing with *A. aerogenes* is by no means established.

Ostermann and Rettger believe that serologic typing is most conclusive in identifying strains of Friedländer bacillus that can be so treated, and studied the antigenic relation of the Friedländer bacillus, *A. aerogenes* and *Esch. coli*. They emphasize the occurrence of variation in colonial morphology, group antigenic relation and the exceptions that seem to occur when any set of standards for identification are applied. The problem awaits further elucidation, even to the study of the normal and pathologic occurrence of the Friedländer bacillus, identified with means now at hand.

If the findings of the Mt Sinai workers can be substantiated in the light of these conditions, a amendment to the older teaching that Friedländer-bacillus infections occur most commonly above the diaphragm and redesignation of the organism as either *Bacillus friedländer* or *B. mucosus capsulatus* are suggested. The list of primary infections caused by this organism gleaned from the literature includes those in the sinus, mastoid and middle ear, throat, lungs, heart, pericardium and intravascular sites, peritoneum, biliary tract and liver, perinephric space, kidneys and lower urinary tract, pelvic organs of the female, and prostate, vesicles and epi-

didymis of the male, brain meninges, bone and soft tissues of the extremities

### SUMMARY

A case of primary generalized peritonitis due to the Friedländer bacillus, the second in the medical literature, is reported

Some aspects of the treatment of such infection with newer agents are briefly discussed

Attention is again directed to the similarity in occurrence and pathogenicity of Friedlander bacillus and *Escherichia coli* and to the probable error of considering the Friedländer bacillus to be primarily a pathogen in the respiratory system The problem of bacteriology and identification is discussed

## MEDICAL PROGRESS

### ABDOMINAL SURGERY (Concluded)

ARTHUR W ALLEN, M D \*

BOSTON

#### THE DUODENUM

Shapiro and Robillard<sup>61</sup> discuss anomalies of the blood supply of the duodenum There are many variations in the vascular arrangement in this region, and unless these are recognized, avascularization of the duodenal stump following gastrectomy may result in necrosis and leakage Avoidance of this complication is simple if the surgeon frees the duodenum from the pancreas only enough to allow an adequate turn-in of the duodenal stump This is best accomplished if the adherent and inflammatory area about the ulcer site is approached after the stomach has been transected Freeing the duodenum distal to the ulcer as a first step in the procedure is more apt to lead to avascularization with subsequent necrosis

Ferguson and Cameron<sup>62</sup> advise giving the patient with a diverticulum of the duodenum a drink of barium the night before operation The barium coats the lining of the diverticulum, making it easier to find They point out that such lesions are a herniation through the muscular coat of the bowel and occur usually on the mesenteric border between two blood vessels They recommend free dissection and inversion of the diverticulum, repair-

ing the defect in the musculature with interrupted fine silk sutures

Mahorner and Kisner<sup>63</sup> suggest the inflation of the duodenum with air introduced through a 22-gauge needle on a 20-cc glass syringe, to outline diverticula They advocate free dissection and amputation distal to a small clamp applied to the neck of the diverticulum The mucosa is inverted with a 00 chromic catgut suture, and the muscularis with interrupted fine silk or cotton sutures

All the authors cited above agree that the incidence of diverticula of the duodenum is from 1 to 2 per cent of the adult population The majority of these lesions are symptomless or cause dyspepsia easily controlled by dietary measures A small percentage of patients may have sufficient disability to warrant corrective surgery

Acute perforation of duodenal ulcer is again discussed by Graham<sup>64</sup> In 125 consecutive cases treated at the Toronto General Hospital the operative mortality was 64 per cent The author considers chemical and nutritional imbalance, rather than bacterial peritonitis, to be responsible for the serious shock-like state of the patient after perforation He believes that better results can be obtained if the patient in poor condition is given supportive therapy for a few hours prior to surgery Attention is called to nature's tendency to seal the

\*Lecturer in surgery, Harvard Medical School chief East Surgical Service, Massachusetts General Hospital

perforation by a deposit of fibrin.<sup>3</sup> He stresses the importance of aiding this process by the application of a tab of omentum to the area. Concomitant gastroenterostomy, gastroduodenostomy, gastric resection, intraperitoneal use of sulfonamides and drainage of the abdomen are all condemned.

Bobmansson<sup>66</sup> has presented an excellent discussion of massive hemorrhage from peptic ulcer. The problem is a combined one that concerns the internist as well as the surgeon. Careful evaluation of such cases should be made to determine whether or not conservative or radical treatment is indicated. Early operation is advocated if the roentgenogram shows a crater or if there is a history of previous perforation or if the ulcer is known to be chronic and when shock-level bleeding cannot be readily combated by blood transfusions. Radical operation is recommended if any surgery is done, since this is the only feasible approach to blood vessels leading to the ulcer area, and exact hemostasis is necessary. By the combined efforts of medicine and surgery, the mortality was reduced from 9.1 per cent in 1939 to 5.1 per cent in 1945. The operative cases were decreased during this period from 45 to 7 per cent of the total. The mortality of the conservatively treated group was reduced from 6 to 5 per cent, and the operative mortality fell from 13 to 5.1 per cent.

Heuer<sup>66</sup> reports that 8 per cent of 337 patients admitted to the New York Hospital with acute massive bleeding from peptic ulcer died. Fifteen per cent of the cases were of the type that would have resulted fatally had not operative interference been carried out. He stresses early decision for or against surgical intervention. The mortality was 10 per cent in patients operated on early in the episodes, as compared with 70 per cent when the operation was undertaken after several days of bleeding. He also emphasizes the necessity for radical gastrectomy in these cases, stating that palliative operations are useless.

There is some tendency to operate early in more cases of acute massive bleeding from gastric and duodenal ulcer than formerly. With the marked reduction in the operative risk now evident, there is a definite argument in favor of such an attitude. The fact that the younger patients in this group almost invariably cease to bleed under conservative treatment, whereas the older patients more frequently died of hemorrhage during the episode, has been stressed.<sup>67</sup> So far, surgeons have not been able to bring about a successful outcome very often if the operation is undertaken after several days of bleeding. It is true that most of the patients operated upon within seventy-two hours of the onset of hemorrhage can be brought through safely. Much time could be saved the younger patients by a radical attack as soon as shock had been properly controlled, since most of them should be operated

upon eventually to prevent recurrences of these disturbing bouts of bleeding.

Dragstedt et al.<sup>68</sup> express their present attitude concerning transabdominal vagus resection for ulcer. Sixty-one transthoracic and 109 transabdominal vagotomies form the basis of their thesis. They also confirm previous reports that the vagus nerves have several anatomic variations but believe that all these cases lend themselves to the abdominal approach. They have no hesitancy in combining vagotomy with gastroenterostomy or gastroduodenostomy when there is evidence of cicatricial obstruction. Eighteen out of their total of 170 cases showed evidence that the vagi had not been completely interrupted. Reoperation with resection of retained vagus fibers resulted in relief in 2 patients. Six of the 18 had recurrence or persistence of ulcer symptoms. The patients were maintained on gastric suction for from four to six days after vagotomy, and a normal diet was not tolerated for from two to eight weeks.

Fallis and Warren<sup>69</sup> state that anastomotic ulcer occurs in 15 per cent of patients having gastroenterostomy for duodenal ulcer. The stomal ulcer always occurs in the efferent loop of jejunum opposite the anastomosis. Patients who have had perforation or bleeding from the original ulcer are prone to have the same manifestation in the new lesion. The authors consider medical treatment unsatisfactory for these patients and, at the time of their report, believed that subtotal resection of the stomach, with aseptic technic and short-loop retrocolic anastomosis, was the treatment of choice.

#### THE SMALL INTESTINE

Pemberton and his associates<sup>70</sup> bring to mind the rare lesion described by George Whipple in 1907, termed "lipodystrophy." They believe that only 14 cases have so far been reported and add 3 cases observed at the Mayo Clinic. The syndrome in brief is that of abdominal pain and weight loss, a doughy-feeling mass in the abdomen and steatorrhea. The findings are those of mesenteric thickening with engorged lymphatic vessels. Microscopical examination of the fatty tissue of the mesentery shows leukocytes and giant cells. X-ray and bile-salt therapy has been suggested but is of questionable value. The usual course is one of long duration and gradual disintegration.

Lazarus and Marks<sup>71</sup> discuss benign intestinal tumors of vascular origin, finding 38 cases reported in the literature. These tumors vary from capillary nevi to cavernous hemangiomas. It is probable that some of the cases of obscure gastrointestinal bleeding can be accounted for on the basis of these lesions which are often small and easy to overlook. The authors describe a patient who continued to bleed after four operative attempts had been made to remove the vascular tumors, which are often multiple and may involve the entire intestine.

Saltzstein and Rao<sup>72</sup> report the history of a patient who bled massively from the intestine. Exploration revealed a surgical sponge, which was encysted but had eroded a 1-cm area of the ileum. The patient had been operated on twenty-five years previously for a pelvic complaint and twenty-three years before for intestinal obstruction. The authors quote Crossen and Crossen,<sup>73</sup> who collected 250 cases of foreign bodies in the abdomen, as stating that these usually gravitate to the pelvis and become extruded through the bowel, vagina or bladder. Fourteen of the 250 foreign bodies had remained within the abdomen for five or more years, and these were all encysted.

A case of leiomyoma of the jejunum operated on for massive hemorrhage supposedly from duodenal ulcer is reported by Marshall and Welch.<sup>74</sup> The lesion was located 15 cm beyond the ligament of Treitz and was successfully resected.

Botsford and Seibel<sup>75</sup> have reported all the tumors of the small intestine, exclusive of those arising from the papilla of Vater and the pancreas, encountered at the Peter Bent Brigham Hospital, Boston, from 1913 to 1946. Sixty-five primary tumors were found, of which 33 were malignant and 32 were benign. The malignant tumors were classified as adenocarcinoma in 18, lymphosarcoma in 13 and carcinoma in 2 cases. The benign lesions were lipomas, adenomas, leiomyomas and fibromas in that order of frequency. There were 10 in the duodenum, 14 in the jejunum and 41 in the ileum. Half the lesions were apparently symptomless and were found incidentally. The observations are in accord with the experience of others that adenocarcinoma is more common in the high intestine and that sarcoma is more often found in the ileum.

Rabinovitch et al.<sup>76</sup> found 15 cases of sarcoma of the bowel in the records of the Jewish Hospital, Brooklyn, New York, in a twenty-five-year period. They state that this lesion has a ratio to carcinoma of 1:55 in the small intestine, 1:275 in the colon and 1:577 in the rectum.

Patent omphalomesenteric duct and its relation to the diverticulum of Meckel is discussed by Kittle and his co-workers,<sup>77</sup> who present an excellent review of the history and embryology of this lesion. Although Meckel's diverticulum occurs in from 1 to 2 per cent of the populace, a patent omphalomesenteric duct has been reported in only 128 cases. The authors cite 3 cases of their own and call attention to the importance of the lesion in producing intestinal obstruction when a loop of small intestine prolapses through the patent ductus. For this reason, they advise operative correction of this congenital defect whenever the diagnosis is made.

Another good review of the literature on Meckel's diverticulum has been made by Haber.<sup>78</sup> He studied critically 23 case histories at his disposal and emphasized the significance of this lesion in the differ-

ential diagnosis of patients with apparent intestinal obstruction.

Devine<sup>79</sup> presents an excellent discussion of paralytic ileus. From the study and observation on 43 cases, he deduces that this syndrome can be divided into three stages. In the first stage, there is normal bowel activity, and the intestine can respond to stimulation. During the second stage, there is disordered movement and drugs that stimulate peristalsis, as well as enemas, will do no good but will increase discomfort and distention, thereby hastening the third stage. In this last phase, there is loss of intestinal motility with the development of full-blown ileus. Experiments following intestinal intubation with various local applications and drugs led to these concepts. Heat and turpentine stupes had no effect on bowel movements. Barbiturates decreased peristalsis and bowel tone. Penicillin and sulfonamides did not affect motility. Overdistention of the stomach produced loss of bowel tone and movement. Stimulation of the colon with enemas also stimulated the small intestine. Devine advises no cathartic before operation, gentle handling of the intestine, limitation of fluids by mouth for twelve hours post-operatively because of swallowed air, atropine and barbiturates to be kept to a minimum, the liberal use of morphine and no stimulation of the intestine by drugs or enemas until peristalsis is normal. Miller-Abbott intubation and intravenous fluids offer the best treatment for paralytic ileus when it occurs.

Watt and Harner<sup>80</sup> report 3 cases of intestinal obstruction from bezoars. Two of these were from the ingestion of persimmons, and the other from hair. All were found in the terminal ileum, and all the patients recovered after surgical removal of the bezoars.

An interesting case of intestinal obstruction from the rapid ingestion of five oranges in a man with a previous Polya operation is reported by Baumeister and Darling.<sup>81</sup> The orange pulp had collected in the ileum and had to be removed surgically to relieve the obstruction. I have encountered a similar case in an edentulous man with a previous gastroenterostomy who admitted swallowing a peeled orange in two halves. At operation it appeared that these sections had come together and lodged in the usual narrow area of the terminal ileum.
